Introduction. With their self-similar architectures, dendrimers constitute good models of complex structures. After Voegel's results,1 further investigations have intended to increase the generation number.1,2 The state of the art is reached with phosphorus-containing dendrimers3 (12th generation). The aim of this work is to analyze the evolution of molecular mobility upon increasing of generation. Thanks to complementary dielectric techniques as thermostimulated currents (TSC) and dynamic dielectric spectroscopy (DDS), the mechanism of dipolar polarization and its evolution as a function of the generation of dendrimers will be studied. DDS shows the shift of relaxation mode on a wide frequency and temperature range as being shown previously.3,4 Owing to its low equivalent frequency and its high sensibility, TSC experiments give complementary information on the elementary components of the complex relaxation. Moreover by using fractional polarization, the experimental distribution function of the activation parameters has been determined. In this communication, we focus on low-temperature relaxations of phosphorus-containing dendrimers of generations 0, 1, and 2.

Experimental Section. Phosphorus-containing dendrimers are characterized by a regularly branched treelike architecture and strongest dipolar moment values found in dendrimers3 (for example μ = 1.082 × 10−28 C·m for a generation number g = 11). From a phosphorus core constituted by the strong P=S dipole, these dendrimers were synthesized by a convergent process which consists on iteration of chemical steps. On the same core, radially branched layers were attached (Figure 1). Dendrimers were synthesized generation after generation. Details of synthesis of this amorphous polymers were published elsewhere.3,4 Numbering of these compounds hereafter will be done as follows: [G]m in which g is the number of generation—here g = 0, 1, and 2—and G corresponds to a dendrimer with terminal aldehyde groups. All the studied samples are available as powder. For g = 0, no calorimetric manifestation of glass transition has been pointed out. For g = 1 and g = 2, the glass transitions Tg of the studied phosphorus-containing dendrimers are 346 and 395 K respectively. In the case of DDS, the sample is constituted by a thin layer of powder (100 ± 10 µm). For TSC experiments, slightly compressed pellets of 800 ± 10 µm thickness were directly inserted between electrodes.

Broadband dielectric measurements were performed using a NOVOCONTROL BDS400 covering a frequency range of 10−2 to 3 × 109 Hz with 10 points per decade. Experiments were carried out with a temperature range 123–373 K. Dielectric isotherms spectra were measured every 5 K. Before each frequency scan, temperature was kept constant to within ±0.2 K. The real ε′ and imaginary ε″ parts of the relative complex permittivity ε̃ were measured as a function of frequency F at a given temperature T.

Complex TSC spectra and fractional polarization analysis were carried out on a Thermold TSC/RMA spectrometer. For global experiments, the sample was polarized by an electrostatic field E0 = 400 kV·m−1 during t0 = 2 min over a temperature range from the polarization temperature T0 = 173 K down to the freezing temperature T0 = 93 K. Then the field was turned off and the depolarization current was recorded with a constant heating rate (gh = +7 K·min−1), so that the equivalent frequency of the TSC spectrum was Feq ~ 10−2 – 10−3 Hz. TSC experiments are complementary from DDS spectroscopy on the low-frequency side. For windowing experiments (4th elementary peak), the polarizing field was applied for t0 = 2 min at T0. Then the sample was short-circuited at T′ = T0 − ∆T0 and the temperature was maintained constant for t = t0. Then the sample was cooled at T0 = T0 − 50 K, and the depolarization current was recorded in the same way as for the complex mode. Two types of windowing experiments11,12 were carried out: narrow poling windows (∆T0 ≤ 5 K) for isolating elementary processes and large poling windows (∆T0 ≥ 20 K) for the “cleaning process”. Wide poling windows might allow us to exhibit the various components of relaxation modes and narrow poling windows give elementary TSC spectra that can be analyzed by the hypothesis of a single relaxation time.

Results and Discussion. Figure 2 displays the dielectric loss spectra of the low-temperature relaxation mode for g = 0 (Figure 2a) and g = 2 (Figure 2b) of phosphorus-containing dendrimers. Experimental data are fitted by the Havriliak–Negami (HN) function13 without any additional conductivity term

\[ ε′(ω) = ε_∞ + \frac{ε_1 - ε_∞}{1 + (iωτ_{HN})^{α_{HN}}} \]  

(1)

where ε∞ is the relative real permittivity at infinite frequency, ε1 is the relative real permittivity at null frequency, τHN is the relaxation time, ω is the angular frequency, and αHN and βHN are the Havriliak–Negami parameters. Numerical values of HN parameters are presented in Table 1.

For g = 0, the dielectric loss profile confirms previous data on different dendritic macromolecules: a quasi-Debye mode β(HN) is pointed out. Since the isotherm T = 248 K, conductivity α appears on the low-frequency tail of ε′(ω). Nevertheless, it does not modify the Havriliak–Negami fitting.

For g = 1 and g = 2, two relaxation regimes are observed: (a|g|, α|g|) the dielectric manifestation of glass transition and a low-temperature mode (β|g|).
For $g = 0$, the sample exhibiting no glass transition, no electric relaxation is observed. Contrarily, all studied phosphorus-containing dendrimers have a secondary $\beta$ relaxation mode, $\beta^{[G_0]}$, $\beta^{[G_1]}$, and $\beta^{[G_2]}$ modes are characterized by relaxation times with an Arrhenius-like dependence

$$\tau(T) = \tau_0 \exp \frac{\Delta H}{RT} \tag{2}$$

where $R$ is the ideal gas constant, $\tau_0$ is the preexponential factor, and $\Delta H$ is the activation enthalpy. $\tau_0$ is on the order of magnitude of $\sim 10^{-13}$ s.

According to the Eyring relationship

$$\tau_0 = \frac{h}{k_B T} \exp \frac{-\Delta S}{R} \tag{3}$$

where $h$ is the Planck constant, $k_B$ is the Boltzmann constant, and $\Delta S$ is the activation entropy. For $[G_0]$, $[G_1]$, and $[G_2]$, $\Delta S$ is near zero, and $\Delta H$ takes the values $\Delta H = 40.4, 32.6, \text{and} 34.9 \text{kJ} \text{mol}^{-1}$ respectively. This parameter is strongly dependent upon the generation. In others dendrimers $\beta$ activation enthalpies of $\beta$-modes vary from 16 to 80 kJ mol$^{-1}$ for $g = 0$ and $g = 2$, respectively. This variation has been attributed to differences in their physical structure. In phosphorus-containing dendrimers, the activation enthalpy of $[G_0]$ remains of the same order of magnitude than for $[G_1]$ and $[G_2]$. It is also important to note that the single peak of $[G_0]$ is perfectly explained by the existence of a single mobile dipolar species which is the aldehyde end group. The low-temperature mode $\beta^{[G_0]}$, $\beta^{[G_1]}$, and $\beta^{[G_2]}$ modes.

Figure 1. Scheme of phosphorus-containing dendrimer architectures (points (●) symbolize P=S groups) and molecular structures for $g = 0$, 1, and 2 (respectively $[G_0], [G_1]$, and $[G_2]$).

Figure 2. (a) Frequency and temperature dependence of the dielectric energy loss for the $\beta$-mode of $[G_0]$. (b) Frequency and temperature dependence of the dielectric energy loss for the $\beta$-mode of $[G_2]$. For $g = 0$, the sample exhibiting no glass transition, no electric relaxation is observed. Contrarily, all studied phosphorus-containing dendrimers have a secondary $\beta$ relaxation mode, $\beta^{[G_0]}$, $\beta^{[G_1]}$, and $\beta^{[G_2]}$ modes.
data. Consequently, this mode has been assigned to local dipolar relaxation.

In the case of \( g = 1 \), a single mode is observed near \( T_m = 131 \) K. Taking as reference \( G'_1 \), both characteristics half-width (\( \Delta T \)) and maximum current (\( I_m \)) of the peak slightly increase from \( \Delta T (G'_1) \sim 20 \) K to \( \Delta T (G'_2) \sim 40 \) K, and \( I_m (G'_1) \sim 6 \times 10^{-14} \) A to \( I_m (G'_2) \sim 1 \times 10^{-13} \) A. The peak temperature maximum is shifted toward lower temperature.

Contrarily to the modes observed for \( g = 0 \) and \( g = 1 \), the one recorded for \( g = 2 \) is metastable. After a series of scans at the same rate in the investigated temperature range, it stabilizes and gives the spectrum reported as a solid line in parts a and b of Figure 3. After poling the virgin dendrimers, a single peak is recorded (dashed line in Figure 3b). The higher temperature component has the same behavior than relaxation processes due to physical aging while the low-temperature component has the characteristics of a relaxation associated with a secondary transition.

To isolate both components, the windowing technique (“cleaning process”) has been applied.

The polarization temperatures are indicated by small arrows on the Figure 3a. The complex TSC spectrum has been resolved by this technique into two submodes (dashed line in Figure 3a): first one \( \beta'_{1,[G]} \) near \( T_1 = 128 \) K and a second one \( \beta'_{2,[G]} \) near \( T_2 = 163 \) K. As expected, this complex mode has two major components. Their envelope (dashed line) follows the same variation as the complex mode (full line) of \( [G] \). But neither \( \beta'_{1,[G]} \) nor \( \beta'_{2,[G]} \) can be compared with \( \beta'_{[G]} \). Temperature positions \( \Delta T (\beta'_{1,[G]}; \beta'_{2,[G]})/20 \) K and intensities are quite different. The analysis of the lower temperature component of \( [G] \) shows that it has a common origin with the relaxation mode observed in \( [G] \). The complexity of the relaxation modes indicates the existence of interactions with other dipolar species, most probably \( P=S \). The substitution of a \( P=S \) core by a \( P=O \) core for \( g = 0 \) shows that there is a significant interaction with this group. Indeed, TSC experiments indicate a low-temperature shift of \( \sim 20 \) K of the very narrow mode. Considering the mobility and the polarity of the aldehyde groups, they might be responsible for the \( \beta \) relaxation modes. To check this hypothesis, a comparative study of dendrimers without aldehyde end groups has been performed (P=O core). In this case, the core dipolar species interacts with the P=O core. The relaxation mode found in \( [G] \) exists also in \( [G] \) and \( [G] \) in the same temperature range. The activation enthalpies remains of the same order of magnitude than for \( [G] \). The slight modification of its characteristic parameters has been associated with differences in the interaction with P=O groups. An additional submode is also observed in \( [G] \) in the same temperature range: due to its metastability, it might be ascribed to a

broadening. A more detailed analysis of the complex relaxation modes, was carried out by TSC experiments.

Figure 3a shows the complex TSC spectrum in full line of phosphorus-containing dendrimers of generations 0, 1, and 2. The polarization temperatures are indicated by the small arrows on the figure. The global TSC spectrum for \( g = 0 \) presents a narrow peak, whose maximum is located at 149 K. Fractional polarization with \( \Delta T = 5 \) K, exhibits a quasi-non-distributed mode. The temperature dependence of relaxation times is expressed by an Arrhenius equation (eq 2). Equations 2 and 3 permit us to extract \( \Delta S \) and \( \Delta H \), and these values are listed in Table 2. Let us consider the major contribution component of this mode located at \( T_m = 146 \) K: \( \tau_0 \) is close to 10\(^{-14}\) s, which is coherent with DDS

---

**Figure 3.** (a) Global TSC spectra of \( [G], [G] \) and \( [G] \) (full line). Experimental resolution of \( [G] \) (long-dashed line) (\( \Delta T \) ≥ 20 K). The small arrows indicate the polarization temperatures. The arrow indicates the polarization temperature.
Structural relaxation. In a near future, these analyses will be extended to the high-temperature range in order to analyze more delocalized molecular mobility. We also plan to investigate dendrimers of the same series corresponding to higher generations, to compare them with equivalent linear and hyper-branched phosphorus-containing macromolecules.
