ABSTRACT: We explore the gold functionalization of 2D CdSe nanoplatelets (NPL) as a possible way to tune their electronic and transport properties. We demonstrate that the size and location of the gold tip can be controlled using light and temperature. The Au tip-CdSe NPL hybrid present a large rise of the conductance compared to the pristine semiconductor (i.e. without gold functionalization). The role of the semiconductor in this transport remains unclear and needs to be better understood. We hypothesize four mechanisms: (i) a reduction of the band gap energy due to the formation of a gold-selenium compound, (ii) a charge transfer between the metal and the semiconductor leading to an increase in carrier concentration and (iii) a change in the inter nanoparticle tunnel barrier height or (iv) a simple percolation process between the metallic grain. X-ray photoelectron spectroscopy (XPS) shows that the CdSe NPL are unaffected by oxidation, and that gold is in the metallic state Au^0 . We consequently exclude the formation of a narrow band gap Au_2Se phase as the possible mechanism leading to the observed rise of conductance. Moreover Kelvin Probe force microscopy and XPS gives evidence for an increase in work function upon gold-tipping, which can be interpreted in terms of a shift of the Fermi level toward the valence band maximum. As hole-conduction in CdSe NPLs is very unlikely to occur, we rather favor the hypothesis that the strong increase in conduction is largely driven by percolation between the metallic tips as the main mechanism responsible for transport in this hybrid system.

1. INTRODUCTION

While the growth of colloidal nanocrystals gets more mature, the possibility to synthesize complex systems in solution become real. In addition to semiconductor heterostructures,¹ one can cite Janus² nanoparticles and metal tipped semiconductors.^{3,4,5} The latter are of utmost interest for transport and photocatalysis. In particular such hybrid materials present enhanced conduction³ and photoconduction⁶ properties resulting from their modified electronic structures⁴. Moreover, metal-semiconductor hybrids⁷ are well suited for photocatalysis, to ensure the splitting of the photogenerated electron-hole pairs.

Gold tipped semiconductor synthesis generally relies on the reduction of a gold salt in presence of semiconductor nanocrystals and a reducing agent, generally an amine. So far most of the efforts have been focused on 1D rod functionalization.^{3,8,9} On metal-functionalized nanorods, it was demonstrated that the electronic impact of the metal on the semiconductor remains limited to a few nanometers in the vicinity of the metal.⁴ As a result, only a limited part of the material behaves as a hybrid structure. In this paper, we investigate the growth of gold-tipped cadmium chalcogenides 2D nanoplatelets^{10,11,12} (NPLs). With the 2D geometry of the NPL we can achieve more tips per nanocrystal than for nanorods (or in other words a higher metal-to-semiconductor ratio) and possibly obtain a stronger coupling between the metal and the semiconductor. The metal functionalization of cadmium chalcogenides NPLs have been recently proposed using gold^{13,14}, palladium¹⁴, platinum^{14,15} and nickel.¹⁶ Here, we demonstrate that by switching from metal reduction to photo-assisted metal reduction and cation exchange it is possible to obtain size and site control of the metal functionalization, which was not previously achieved. Moreover we expand the method and evidence that not only CdSe NPLs but also their heterostructures (CdSe/CdZnS core/shell geometries) can be functionalized by metals thanks to the proposed procedure.

We also focus on the transport properties of this hybrid system. As expected, we observe a significant boost of the conductance in presence of the gold functionalization. This result is consistent with previous transport measurements on such metal-semiconductor hybrid systems either conducted on single nanoparticle³ or on an array of nanoparticles.^{6,17} The origin of this increase of conductance remains mostly unknown. Several explanations have been proposed, including a decrease of the Schottky barrier height³ and percolation between metal domains¹⁸. In particular, the role of the semiconductor remains unclear. We speculate four mechanisms involving the semiconductor to

explain the observed rise of conductance: (i) an increase of the semiconductor carrier density due to a reduction of the semiconductor band gap energy induced by the formation of a narrower band gap phase containing a gold chalcogenide. (ii) An increase of the semiconductor carrier density resulting from a charge transfer process, or (iii) a stronger coupling between NPLs due to a possible lowering of the inter-NPL tunnel barrier. Alternatively the semiconductor may not be involved in the conduction mechanism and the transport only results from a percolation process between the metallic sites. To discriminate between these different scenarios, we use X-ray photoemission spectroscopy (XPS) and Kelvin probe force microscopy (KPFM). These two techniques allow us to precisely study the chemical and electronic structure of the Au tip-CdSe NPL hybrid nanomaterial.

2. Methods

2.1. Chemicals

- **inorganic precursors**

Selenium powder (Sigma-Aldrich, 99.99%), Cadmium nitrate tetrahydrate ($\text{Cd}(\text{NO}_3)_2(\text{H}_2\text{O})_4$, Aldrich 99,999%), Cadmium acetate dihydrate ($\text{Cd}(\text{OAc})_2(\text{H}_2\text{O})_2$, Aldrich 98%), thioacetamide (TAA, Aldrich, 99%), Zinc nitrate hexahydrate ($\text{Zn}(\text{NO}_3)_2(\text{H}_2\text{O})_6$, Aldrich 99%), Gold chloride (AuCl_3 , Strem Chemicals).

- **Solvents**

n-Hexane (VWR, 98%), Ethanol (EtOH Carlo Erba, 99.5%), Isopropanol (VWR, 100%), Toluene (VWR, 99.8%), Chloroform (VWR, normapur), 1-Octadecene (ODE, Aldrich, 90%).

- **Organic Ligands**

Oleic acid (Aldrich, 90%), Octylamine (Aldrich, 99%), Myristic acid (Sigma-Aldrich, 95%), Dodecylamine (DDA, Aldrich, 98%), Didodecyldimethylammonium bromide (DDAB, Aldrich, 98%), Ethanedithiol (EDT, Aldrich 98%).

2.2. Nanoparticle synthesis

- ***CdSe nanoplatelets synthesis with a first excitonic feature at 510 nm***

The CdSe nanoplatelets are synthesized according to a method previously described.¹⁰ Briefly, 960 mg of $\text{Cd}(\text{OAc})_2(\text{H}_2\text{O})_2$, 2.36 g of oleic acid and 90 mL of ODE are degassed under vacuum at 100°C for 1 h. Then 144 mg of Se is added and the mixture is heated to 240 °C under Argon for 15 min. At 180°C, 360 mg of $\text{Cd}(\text{OAc})_2(\text{H}_2\text{O})_2$ are quickly added. The reaction is stopped by removing the heating mantle and 5 ml of oleic acid is injected. Nanoplatelets are then separated from spherical quantum dots by selective precipitation and suspended in 10 mL of hexanes.

The typical obtained material is made of NPLs which are 1.2 nm thick and with a rectangular shape (10 nm x 40 nm), see Figure 1a. The material shows a first exciton at 510 nm, see Figure 1e and S1.

- **Growth of a $\text{Cd}_{0.5}\text{Zn}_{0.5}\text{S}$ shell**

The protocol is adapted from ref 19: 10 mL of CdSe NPLs in hexane are mixed with 25 mL of CHCl_3 , 300 mg of thioacetamide (TAA) and 3 mL of octylamine and sonicated until complete dissolution of the TAA. 1 mL of $\text{Zn}(\text{NO}_3)_2$ 0.2 M in EtOH and 1 mL of $\text{Cd}(\text{NO}_3)_2$ 0.2 M in EtOH are added and the mixture is heated to 60 °C for 4 h. The nanoplatelets are then precipitated with isopropanol and dispersed in toluene. Their typical thickness is around 5 nm, while their lateral extension is almost unchanged compared to the CdSe NPLs core (12 nm x 40 nm).

2.3. Gold functionalization

- ***Gold reduction producing small metallic tips***

To add the gold tip to the CdSe NPLs, we developed a procedure which is inspired from the one developed for the gold tipped rods.^{3,8} Typically, 36 mg of AuCl_3 , 120 mg of didodecyldimethylammonium bromide (DDAB) and 210 mg of dodecylamine (DDA) are mixed in 10 mL toluene. The obtained yellow orange solution is called A. This solution is not stable over a long time and need to be freshly prepared.

In a 50 mL three neck flask, 1 mL of a NPLs solution with an optical density of 20 (at the first excitonic peak) is mixed with 4 mL of toluene under Argon atmosphere. 0.1 mL of A is mixed with 3.2 mL of toluene and then injected in the flask dropwise over 5 minutes. The solution turns from yellow to a light brown orange. The final mixture is precipitated by addition of ethanol and centrifuged. The supernatant is discarded and the solid is dispersed again in toluene. This purification step is repeated a second time. Final storage is done in toluene. With this method, the gold functionalization is located on the edges of the NPL –preferentially at the corner. NPLs present between 1 to 4 gold beads, which size remains small (2 to 5 nm), see Figure 1b. With such a functionalization the NPLs formed a weakly connected network, where the gold beads act as crosslinker agent, see Figure 1a.

- ***Gold photoreduction producing large metallic tips***

The synthesis is adapted from Menagen *et al.*⁵ with minor modifications. Typically, in a 20 mL vial, 12 mg of AuCl_3 , 30 mg of DDA, 19 mg of DDAB and 4.5 mL of toluene are mixed and sonicated for 2 min. The mixture is then added to 250 μL of nanoplatelets ($\text{CdSe}/\text{Cd}_{0.5}\text{Zn}_{0.5}\text{S}$) with a Zn rich surface and a

concentration of $\approx 5 \mu\text{M}$, dispersed in 2.5 mL of toluene. The vial is then put in an ice bath in front of a 150 W Xenon lamp and the light is focused on it for 4 h.

While switching from dark reduction to photon assisted gold reduction we observe an increase of the gold tips size from below 5 nm to the 10-20 nm range. 20% of the CdSe NPLs present no tip, 60% present a single tip and 20% have 2 tips and more. Generally the NPLs present only one gold tip located at one of the corners, see Figure 2.

- ***Gold thermal cation exchange***

The synthesis is exactly the same as the one described above for the Au photoreduction, but S rich NPLs are used and the reaction is conducted under dark condition at $\approx 70^\circ\text{C}$. Using this condition the gold functionalization is rather located in the center of the NPL, see TEM images in Figure 3.

2.4. Material characterization

UV-Visible absorption spectra are measured using a Cary 5E spectrometer.

Samples for X-ray diffraction, are prepared by dropcasting the nanoparticle solution on a Si wafer to form a 1 cm x 1 cm film. The X-ray diffraction acquisition is conducted using a Philips X'pert system using the Cu K_α line ($\lambda=0.154 \text{ nm}$) as photon source. The diffractometer is operated under 40 kV and 40 mA.

Transmission electron microscopy (TEM) was obtained by dropcasting the nanoparticle solution onto a copper TEM grid. Grids were degassed overnight under secondary vacuum before imaging. Non high-resolution imaging was obtained on a JEOL 2010 microscope, while a JEOL JEM 2200FS, with a Cs aberration corrector was used to obtained high resolution image in STEM HAADF mode. Nanometer resolved energy dispersive X-ray spectroscopy (EDX-EDS) was also conducted on this microscope.

For ensemble EDX analysis we use an Oxford EDX photon probe on a FEI Magellan scanning electron microscope (SEM). The typical operating condition for the SEM relies on 15 kV electron acceleration operated with a 1.6 nA current.

We used the X-Ray Photoelectron Spectroscopy (XPS) setup located at the Laboratoire de Chimie Physique Matière et Rayonnement (UPMC). The measurements were carried out in UHV conditions ($P=3 \times 10^{-10} \text{ mbar}$) using a non-monochromatized Mg K_α source (the main $K_{\alpha 1,2}$ line energy is 1253.6 eV, and its full-width at half maximum is 0.75 eV) and a SPECS PHOIBOS150 hemispherical electron analyzer (radius of 150 mm). We used a pass-energy of 50 V and an entrance slit of 3 mm. The overall energy resolution (source plus analyzer) was 0.90 eV. For the XPS analysis, the nanoplatelets solution

was dropcasted on a cleaned Si wafer. Once the film was dried, it was dipped into a 0.5% in volume solution of ethanedithiol in ethanol for 30 s. Then the film is rinsed in pure ethanol before being dried again. The deposition process is repeated several times until a roughly 100 nm thick film is formed. Two types of films were produced, one with CdSe nanoplatelets decorated with Au nano-tips (termed “Au tip-CdSe NPL”), and one with plain CdSe platelets (lacking Au nano-tips, and termed “CdSe NPL”). Due to the resistivity of the films, charging effects were observed. This issue was solved by biasing the Si wafer positively to attract more stray electrons. The binding energy (with respect to the Fermi level) was determined after deposition of an “electrically floating” macroscopic gold disk on top of the layer (with a known Au $4f_{7/2}$ binding energy of 84.00 eV). A detailed description of the discharging procedure is given in the Supporting Information. The accurate measurement of the Au $4f_{7/2}$ binding energy is carried out in this setup, after a careful measurement of the Fermi edge position using a freshly ion sputtered gold lamella.

Kelvin probe force microscopy (KPFM) was carried out using a Bruker multimode system. A Pt tip of radius 20 nm is used as a conductive probe. The nanoparticles are dropcasted on a freshly cleaved MoS_2 wafer, of known work function (4.8 eV). To achieve a smooth single layer coating of the substrate the nanoparticles are used as such (*i.e.* without ligand exchange).

2.5. Transport measurements

- ***Electrodes preparation***

We prepare interdigitated electrodes using standard lithography method. The electrodes include 25 pairs of 2.5 mm long electrodes. Each of the digits is spaced by 10 μm from its neighbor. Electrodes are deposited on a Si/SiO₂ wafer (400 nm oxide) and are made of 3 nm Cr covered by 35 nm gold.

- ***Ligand exchange for transport***

For transport, we perform a ligand exchange on film. Briefly we prepare a solution of ethanedithiol at 0.5% in volume in ethanol. The nanoparticles, dispersed in hexane, are dropcasted on the electrodes and the film is dried. The film is then dipped for 3 min in the EDT solution, rinse in pure ethanol and finally dried under nitrogen flow. The deposition process and the subsequent ligand exchange are repeated two other times. The final film thickness is around 50nm. Electrical measurements are acquired with a Keithley 2400 source-meter.

3. RESULTS AND DISCUSSION

3.1. Synthesis and optical properties

Similarly to the case of nanorods, we have prepared gold-tipped nanoplatelets by reduction of a gold salt in presence of amine and long ammonium ligands. This procedure leads to the formation of metallic tips preferentially located on the corners of the CdSe NPLs. Under ambient conditions—room temperature and no excess light—the gold tips remain small in size (2-5 nm, see the Figure 1a-b). This size is typically smaller than the one reported by Naskar *et al*¹⁴ who conducted the Au tip growth in absence of ammonium ligands. The hybrid Au tip-CdSe NPLs tend to bridge between each other and form a network, see Figure 1a, as previously observed for rods.¹⁷

Figure 1 a. TEM image of Au tip-CdSe NPLs. The inset is a zoom on the Au tip. b. TEM image of Au tip-CdSe NPLs. The highlighted areas have been probed using EDX and the Cd, Se and Au content is given in Table 1. c. X-Ray diffractogram of CdSe NPLs and once functionalized with the gold tip. d. Ensemble energy dispersive X-ray spectroscopy of CdSe NPLs functionalized with Au tips. e. Absorption spectra for a series of CdSe core NPLs functionalized by Au nanoparticles at their tip for different level of gold introduced. The volume corresponds to the volume of solution A (see experimental section) introduced in the CdSe flask.

X-ray diffraction (XRD) confirms the formation of a metallic gold crystalline phase, as shown by the diffraction peak at $2\theta \approx 38^\circ$ ((111) peak of Au), see Figure 1c. Moreover the CdSe diffraction pattern remains unaffected. Energy dispersive X-ray spectroscopy (EDX), see Figure 1d, further confirms the presence of gold. The amount of gold is estimated to be around 8% of the CdSe molar content in this Au tip-CdSe NPL hybrid system. From this amount we can estimate the reaction yield of the gold reduction to be around 20%, see the supporting information for details. Using EDX coupled with TEM we check that the gold is only located around the tip and does not form a thin layer over the semiconductor, see Table 1 and Figure 1b.

Table 1 Molar ratio of CdSe and Au obtained from energy dispersive X-ray spectroscopy on the site shown on Figure 1b.

Position	CdSe ratio (%)	Au ratio (%)
1	100	0
2	61.6	38.4

When the amount of gold increases, the absorption spectrum of the NPLs tends to broaden but the excitonic signal remains visible even at high gold concentration, see Figure 1e. Such an absorption spectrum typically results from the sum of the excitonic component of the nanoplatelets and the plasmonic feature of the gold.²⁰ It is worth noting that the photoluminescence signal from the CdSe NPLs disappeared quickly after the gold introduction. This drop results from the exciton energy transfer (i.e. both the electron and hole are transferred) from the excited state of the semiconductor to the metal,^{21,22} due to the spectral overlap of the NPLs photoluminescence and the gold absorption. This energy is then dissipated as thermal losses in the metal.

This first synthesis based on spontaneous gold reduction at room temperature by the amines is not suitable to achieve large gold tips. Indeed this method leads to big unconnected gold nanoparticles when a large amount of gold is introduced. To further increase the size of the metallic tips, we have conducted the synthesis through a photoreduction process under strong illumination (150 W Xenon lamp). In this case, larger (10-20 nm) metallic tips are formed at the edges of the NPLs, see Figure 2a. As for gold reduction operated under dark conditions, the absorption spectrum is a sum of the excitonic contribution and the plasmonic contribution (see Figure 2b).

Figure 2 a. TEM image of CdSe/CdZnS nanoplatelets functionalized using gold photoreduction. b. Absorption spectra of raw CdSe/CdZnS NPLs and of the same material once functionalized using the gold photoreduction.

So far, all the metallic functionalization reported on 2D nanocrystals were located on the nanocrystal edges¹³⁻¹⁶. In the two previously described procedures, the metallic tips growth is conducted at room temperature. If a similar metal functionalization is conducted at higher temperature we rather favor a cation exchange process.^{23,24} This exchange has been demonstrated on chalcogenides nanocrystals using small cations such as Cu^+ and Ag^+ ions,²⁵ but it can also occur with relatively less studied gold ions.^{24,26} For cation exchange on 2D NPLs it was demonstrated that there is a minimum thickness of the latter ones to preserve the 2D shape.²⁷ As a consequence, we use core-shell structures¹⁹ (CdSe/CdZnS) in the following because of their larger thickness. It is also worth noticing that the gold reduction previously described not only works with purely CdSe core NPLs, but also with heterostructured (CdSe/CdZnS) nanocrystals, see Figure 2 and figure S2.

Figure 3 a. TEM image of the obtained heterostructures after thermal cation exchange with Au on CdSe/CdZnS NPLs. b. X-Ray diffractogram of the same material, revealing an Au/Au₂S composition. c. Absorption spectra of CdSe/CdZnS NPLs and of the heterostructures obtained after Au thermal cation exchange.

Once gold cation exchange is achieved, we observe a different gold functionalization compared to the previous processes, for which the metal tips is external to the semiconductor NPLs. Here, after cation exchange, the metal site is not forming an edge tip and is rather located in the center of the main facet of the NPL, see Figure 3a. The cation exchange is confirmed by XRD, evidencing the appearance of an Au_2S phase²⁸, as highlighted by the diffraction peak at $2\theta \approx 31^\circ$ ((111) peak of Au_2S), see Figure 3b. The metallic nature of the center of the hybrid nanoparticle is in the same time evidenced by the diffraction peak at $2\theta \approx 38^\circ$ ((111) peak of Au), relative to Au^0 phase. Moreover the diffraction peaks relative to the initial CdSe/CdZnS NPLs have disappeared, which indicates that most of the cations have been exchanged to form a gold chalcogenide phase. The optical absorption further confirmed the successful cation exchange, since we no longer observe the excitonic peak relative to the CdSe/CdZnS NPLs, see Figure 3c. On the other hand, the absorption edge is strongly redshifted according to the narrow band gap semiconductor nature of Au_2S .

Even though the formation of the Au_2S phase can appear as detrimental for catalytic application it serves to underline that a cation exchange mechanism may compete with direct metal reduction. This change in the material composition needs to be considered while discussing the transport in such semiconductor-metal networks.

3.2. Electronic transport

In the following we choose to investigate the transport properties of the Au tip-CdSe NPLs^{29,30} hybrid systems (based on CdSe core only) and to focus on the material obtained thanks to the gold reduction in the dark leading to small Au tips on the NPLs edges.

In the absence of gold and in spite of ligand exchange toward short capping ligands, aiming at reducing the inter-NPL distance and thus increasing the film mobility, the CdSe NPLs network is poorly conductive, see Figure 4. This effect results from the wide band gap nature of CdSe, which, in absence of gating^{31,32} leads to a complete lack of carrier density. On the other hand, once the gold functionalization is added, we observe a significant rise of the conductance in the Au tip-CdSe NPLs film by more than two orders of magnitude (see Figure 4a). This rise is particularly striking at large gold ratio (>15%). The overall dependence of the conductance with the gold ratio can be well fitted with a sigmoidal curve (see Figure 4d) which pledges for a threshold behavior such as the one expected from a percolation process. Simultaneously with the rise of the dark conductance. We observe a vanishing of the photoresponse, see Figure 4b-d. We believe that the disappearing of the photoresponse is a combination of the (i) energy transfer process from the semiconductor to the gold which is also

responsible for the absence of photoluminescence and (ii) from the large increase of the dark conductance. Finally we measured the temperature dependence of the current for a sample at high gold ratio, see Figure S3. The current follows an Arrhenius behavior with a low activation energy ($E_a=280$ meV). The latter value has to be compared with the half band gap value (1.1 eV after ligand exchange) expected for an undoped semiconductor. This strong deviation suggests either a strong doping of the semiconductor or a change in the transport mechanism.

Figure 4 a. Current as a function of applied bias for thin film of CdSe NPLs and Au tip-CdSe NPLs. b Current as a function of applied bias for thin film of CdSe NPLs under dark condition and under illumination by a green laser ($\lambda=532$ nm). c. Current as a function of applied bias for thin film of Au tip-CdSe NPLs (≈50% of gold) under dark condition and under illumination by a green laser ($\lambda=532$ nm). d. conductance and photocurrent of the Au tip-CdSe NPLs film as a function of the gold ratio.

Over the past years, metallic gold functionalization has appeared as a possible strategy to enhance the conduction in networks of anisotropic colloidal semiconductors.^{3,6} However the mechanism leading to the rise of conductance still remains unclear. Sheldons *et al*,³ using transport measurements through a single nano-dumbbell, conclude that the superior conduction performance of Au-tipped CdSe hybrids with respect to plain CdSe results from a lower Schottky barrier in the former case. However, since the nanoparticles size is smaller than the depletion width, it is unclear how Schottky barrier formation models can apply to such metal-semiconductor interfaces (see ref. 33 and references therein). Indeed,

in a recent study of the electronic transport in a network of Au tipped CdSe nanorods, Lavieville *et al*¹⁷ report a deviation from the expected bias dependence of the current with respect to the bulk behavior.

The presence of a threshold in the transport data may suggest a switch of transport mechanism toward a percolative transport between metallic grains. However more evidences are requested before drawing such conclusion and alternative mechanisms also need to be excluded. Therefore the exact role played by the gold nanoparticles needs to be further clarified. We can speculate about three alternative scenarios to percolation. In the first scenario, cation exchange may also occur in parallel to gold reduction. The band edge energy of the material will be reduced, which favor an increase of the thermally activated carrier density, which also leads to a higher conductance. In a second scenario, we may consider a charge transfer process from the gold to the semiconductor³⁴ as a possible mechanism to increase the electron carrier density within the semiconductor. The third scenario considers that gold behaves as a “conductive ligand”, by reducing the inter-nanoplatelet tunnel barrier³⁵ (typically the height is 2 eV while the width correspond to the ligand length ≈ 2 nm). Gold may reduce this barrier, as proposed for inorganic capping ligands,^{36,37} and thus lead to a conductance increases. To discriminate between these three mechanisms, we need a deeper understanding of the chemical and electronic structure of the Au tip-CdSe NPL hybrid system. To do so, we use X-ray photoemission spectroscopy (XPS) and Kelvin probe force microscopy (KPFM) in combination.

3.3. Electronic structure

XPS provides information on the chemical state of cadmium, selenium and gold via the analysis of their core-level binding energies. Due to the relatively low resistivity of the layers deposited on the (conductive) silicon wafer, differential charging phenomena are observed. To eliminate charging we use an original procedure, biasing the wafer positively with respect to the analyzer and the chamber walls that are both grounded. Therefore the flow of “stray electrons” attracted by the sample increases (“stray electrons” are produced in the chamber by the vacuum gauge filaments and by the irradiation of the X-ray tube window). Then the surface tends to be discharged. The elimination of differential charging in the XPS-probed layer can be monitored by minimizing the FWHM of the core-levels. We find that a bias of +5.9 V is optimal. This “flood gun” effect is discussed in detail in the Supporting Information (§S5.2 and figures S4-S8). To determine core-level binding energies referenced to the Fermi level of the film, we deposit an electrically floating macroscopic gold disk on the sample, whose Au 4f_{7/2} binding energy is positioned at 84.00 eV after a proper re-scaling of the energy.

Figure 5. Background-subtracted Cd 3d (a) and Se 3d (b) spectra of the dithiol Au tip-CdSe NPL film sample with its silicon substrate biased to +5.9 V. The binding energy is rescaled to position at 84.00 eV the 4f_{7/2} peak of the sample bearing a (floating) macroscopic gold disk. (c) and (d) are respectively the same of the raw CdSe film. In all case, the excitation source is a non-monochromatized Mg K_α X-ray tube. The Mg K_α3,4 replicas are indicated.

For the Au tip-CdSe NPL film with dithiol ligands, see Figure 5(a), we find that the Cd 3d_{5/2} core-level is at 405.12 eV. This value is close to the one attributed to bulk CdSe:³⁸ 405.3 eV. Due to their fabrication procedure and unavoidable exposure to air, the CdSe NPLs could have been oxidized. In fact we do not find evidence for the presence of CdO, whose Cd 3d_{5/2} binding energy is 404.2 eV (a rare case in which the binding energy of the oxide is smaller than that of the metallic state, namely 404.9 eV).

The Se 3d core-level gives further information on the chemistry of the gold-tipped NPLs. The spectrum of the Au tip-CdSe NPL film with dithiol ligands is presented in Figure 5 b after the due corrections for charging. The presence of SeO₂, with a Se 3d_{5/2} binding energy³⁹ of ≈58.8 eV is excluded, showing that the platelets resistance to oxidation is high (an exposure to air for 48 hours does not alter the picture). The small binding energy doublet (green component) could be attributed to surface Se atoms in contact with the ligands. Note that the binding energy of Se 3d_{5/2} in amorphous selenium is in the range 55.4-55.5 eV.⁴⁰ The carbon and sulfur XPS signal relative to the thiol ligands of the Au tip-CdSe NPLs are discussed in the supplementary information, see figure S9 and S10.

A comparison with the CdSe NPL film with dithiol ligands deprived of gold tips is interesting. Due to charging effects, the same procedure as that used for the Au tip-CdSe NPL film is used (+5.9 V Si substrate bias, binding energy calibration with respect to the Au 4f_{7/2} peak of a macroscopic gold disk deposited on the surface). The Cd 3d spectrum is shown in figure 5 c. It has exactly the same shape as that of the gold-tipped NPL (figure 5 a). Therefore formation of gold nano-tips has no detectable effect on the chemistry of the CdSe nanoplatelets (e.g. oxidation). The only difference is a rigid shift of the binding energy. Indeed the Cd 3d_{5/2} binding energy position of the CdSe film is found at 405.43 eV

instead of 405.12 eV for the Au tip-CdSe NPL film. The same shift of ≈ 0.3 eV is seen for the Se 3d level (figure 5d). The Se 3d_{5/2} component of the CdSe film is at 54.20 eV, while it was at 53.92 eV for the Au tip-CdSe NPL film. Core-level binding energy shifts can be ascribed to changes in the position of the Fermi level in the gap of the semiconductor.⁴¹ This point will be discussed in detail in the next section.

Figure 6 (a) Background-subtracted Au 4f spectrum (filled circles) of the dithiol- Au tip-CdSe NPL sample with its silicon substrate biased to +5.90 V. The BE scale is then shifted by -6.12 eV. (b) Background-subtracted Au 4f spectrum (filled circles) of the Au tip-CdSe NPL sample on which a thick floating gold disk of diameter 0.5 mm is deposited. The Si substrate is polarized by +5.90 V. The BE scale is re-scaled to position the 4f_{7/2} peak at 84.00 eV. The excitation source is a non-monochromatized Mg K α X-ray tube. The Mg K $\alpha_{3,4}$ replicas are indicated.

In Figure 6, we compare the Au 4f core-level spectra of the Au tip-CdSe NPL film, where gold is under the form of nano-tips and that of the thick, macroscopic floating gold disk subsequently deposited on the Au tip-CdSe NPL layer. The spectra are shown after correction of the charging effect. Let us first consider the spectrum of the gold disk, whose 4f_{7/2} line is positioned at 84.00 eV. We observe that the 4f_{5/2} line of the Au nano-tips is found at 84.25 eV, instead of 84.00 eV for the macroscopic Au disk. The shift of +0.25 eV is significant, because the core-level binding energies of the other elements (Cd, Se, C, S) present in the Au tip-CdSe NPL film are identical (to a precision better than ± 40 meV, see SI, figure S8) before and after deposition of the macroscopic gold disk for the same Si substrate bias. Passing from bulk gold to nano-tips, we also observe a small increase in the FWHM from 1.28 eV to 1.45 eV (see Figure 6). However the observed shift is too small to correspond to any oxidation state of gold. Indeed, the literature indicates that the Au⁺ and Au³⁺ oxidation states are found at higher binding

energy than (metallic) Au⁰ by ≈ 1.2 eV and 2.1 eV respectively.⁴² The oxidation of gold in O₃ gives a well-defined 4f_{7/2} peak⁴³ at 85.22 eV. The binding energy increase from bulk gold to nano-tips could rather be attributable to a size effect, given the dimensions of the gold beads, in the 2 to 5 nm range.^{44,45} The analysis of the Au 4f core-level spectrum indicates that the formed hybrid Au tip-CdSe NPL material is only composed of CdSe and Au⁰. Therefore, the formation of an Au₂Se compound, as proposed in our first scenario, is excluded.

Should there exist an electron transfer from the metal to CdSe (second scenario), inducing an (electron) carrier density increase, the Fermi level position in the gap would be affected and would move away from the valence band maximum. This in turn would change the work function (by definition, the energy difference between the vacuum level and the Fermi level) *that would diminish*, assuming that the electron affinity of the NPL is not modified by the addition of the gold-tips and that the gap energy remains the same. The latter hypothesis appears reasonable as XPS excludes the formation of Au₂Se, that has a smaller gap than CdSe. Kelvin Probe Force microscopy (KPFM) measurements⁴⁶ were carried out to measure the work function change between the “raw” CdSe films and Au tip-CdSe NPL films. KPFM measures the contact potential energy difference ($q \cdot V_{CPD}$) which is the work function of the tip (ϕ_{tip}) minus that of the sample (ϕ_{sample}): $qV_{CPD} = \phi_{tip} - \phi_{sample}$. To avoid a calibration of the tip work function, we rather choose to use a substrate with a known work function as a reference. To do so, we use a freshly cleaved MoS₂ substrate, whose work function ϕ_{MoS_2} is 4.8 eV.⁴⁷ We carefully deposited (sub-monolayer) films of CdSe and Au tip-CdSe NPL on MoS₂. Then we measured, in peak force mode, the topography (see Figure 7a) and by polarizing the tip, the surface potential, see Figure 7b. The use of a conductive tip in KPFM tends to reduce the spatial resolution (≈ 20 nm) compared to the topographic mode. As a result, the measured V_{CPD} value is an average value over a whole (functionalized) nanoparticle. The sample work function is finally given by $\phi_{film} = \phi_{MoS_2} + qV_{CPD}(MoS_2) - qV_{CPD}(film)$. By measuring different areas of our sample we are able to produce a histogram of the qV_{CPD} for each sample, see Figure 7 a.

Figure 7 a. Peak force image of Au tip-CdSe NPL film. b Kelvin probe microscopy image of the same area of the film. The inset is a potential profile corresponding to the grey line shown on the image. c Histogram of the sample work function with respect to the MoS₂ work function, probed using KPFM, for a film of core CdSe NPL and for the Au tip-CdSe NPL film. d. Band diagram of CdSe NPL and Au tip-CdSe NPL with respect to MoS₂. The scheme highlights a ≈ 400 meV shift of the band of CdSe once functionalized by gold.

The KPFM work function of the CdSe NPL film is ≈ 4.2 eV, in excellent agreement with a “macroscopic” measurement (4.21 eV) using the low energy cutoff of the secondary electron energy distribution curve obtained during a photoemission experiment, see figure S11 of the supporting information. Figure 7 c shows that the work function of the Au tip-CdSe NPL film is 420 meV larger than that of the CdSe film. The fact that gold-tipping increases the work function indicates that the Fermi level (E_F) valence band maximum (E_{VBM}) energy difference $E_{VB}^{FL} = E_F - E_{VBM}$ decreases by ≈ 0.42 eV between CdSe NPL and Au tip-CdSe NPL.

Concerning the samples studied by XPS (preceding section), we observed that the binding energy of the Cd 3d and Se 3d core-levels decreased by ≈ 0.3 eV passing from the CdSe film to the Au tip-CdSe

NPL film. Core-level shifts are only due to changes in the Fermi level position when the valence band maximum to core-level energy difference remains constant.^{48,49} This is indeed the case as the chemistry is not affected (one single chemical component is seen for the Au tip CdSe film). Therefore the decrease in core-level binding energy can be explained by a E_{VB}^{FL} value smaller by 0.3 eV for the gold-decorated platelets, in good qualitative agreement with the KPFM measurements. The Fermi level gets closer to the valence band maximum. The fact that the ligands are different (ethanedithiol for the XPS samples, oleate for the KPFM ones) is not relevant to the discussion, as each technique compares NPLs with and without gold but with identical ligand coverages.

The KPFM and XPS measurements point to a Fermi level getting closer to the valence band maximum. Note that the *same* motion of the Fermi level towards the valence band is observed in the UPS work of Ehamparam *et al*,⁵⁰ despite these authors draw conclusions contrasting with ours. Two schematical explanations can be proposed: (i) *an electron charge transfer from the semiconductor to the metal occurs, or (ii) the doping of CdSe by gold atoms behaving as acceptors occurs.*

Let us examine the first point. A decrease in E_{VB}^{FL} means a decrease in the electron carrier density, and even possibly hole-doping, while gold receives the electronic charge. A charge transfer to gold explains the decrease in intensity of the white line features previously observed in Au L₃ edge x-ray absorption spectrum (2p_{3/2} to 5d_{5/2} dipole transition) passing from “bulk” gold to nano-beads attached to CdSe⁵¹ NPLs. Indeed the Au 5d holes (due to d-s-p hybridization, leading to a 5d^{10-x} 6(sp)^{1+x} electron configuration) present in gold bulk get filled by electron charges transferred from the semiconductor. A “macroscopic” picture, based on the physics of the Schottky junction formation, is helpful to understand the phenomenon. The “raw” CdSe NPLs are believed to be intrinsic or lightly n-doped. A decrease in E_{VB}^{FL} could be explained by an upward band bending upon the formation of the metal/semiconductor interface assuming flat band conditions for the “raw” CdSe material. To affect the Cd 3d core-level (averaged over the whole NPL) the (electron) depletion width should be comparable to the longest dimension of the NPL (40 nm) given that the gold/CdSe interfaces are positioned at the edge of the platelets.

The second hypothesis (doping) must be also examined. During the gold-tipping process, the CdSe NPLs could be unwillingly doped by gold atoms (the insertion should be limited as an Au₂Se phase is not detected). In bulk II-VI semiconductors, interstitial gold atoms behave as donors, while substitutional gold atoms behave as acceptors.⁵² With substitutional gold atoms, the CdSe NPLs could become p-doped, explaining the smaller E_{VB}^{FL} value. In fact, p-doping of CdSe nanoparticles by silver atoms (that behave like gold atoms) at high dopant concentration is proven in Ref. 53. However it must be

acknowledged that these p-doped CdSe NP by Ag do not exhibit evidence of hole-conduction. The reason for this behavior remains unclear.⁵³

To decide whether gold-tipping influences (via Schottky barrier formation³ or impurity doping⁵⁴) the conductivity of the NPLs or not, the question of hole mobility in CdSe needs to be clarified. In bulk CdSe, the hole drift mobility⁵⁵ at 300 K is not negligible ($75 \text{ cm}^2/\text{Vs}$) compared to that of the electrons (in the range 130 to $720 \text{ cm}^2/\text{Vs}$). However in CdSe nanocrystals, all the literature^{31,32,56} agrees on the n-type nature of the conduction, meaning that the holes present an extremely low transport mobility. We can thus fully exclude the hypothesis of a hole charge transfer which would be responsible for the observed rise of conductance.

Actually the hole transfer toward the semiconductor implies that the semiconductor is empty of any carrier with reasonable mobility in the Au tip-CdSe NPL system. It brings us to the conclusion that the semiconductor actually plays no role in the charge transport (or it may marginally impacts the conduction by increasing the overall dielectric constant of the medium). This conclusion is in good agreement with the results from the Klinker's group obtained on the Pt-CdSe system,⁶ for which the transport may also be dominated by tunnel events between the metallic grains. Since the gold tips on a single NPL are spaced by a fairly large distance ($\approx 10 \text{ nm}$) for tunnel transport, the 3D nature of our film is critical to achieve a percolative path.

The present study also suggests other tracks to follow in order to demonstrate metal-semiconductor hybrid system with a higher degree of mixing of the electronic properties. A greater intrication of the two materials, without ligand spacing and with epitaxial connexion is probably necessary to achieve truly hybridized materials.

4. Conclusions

We propose various strategies to control the size and location of gold tips on CdSe NPLs. Traditional gold reduction carried out at room temperature (20°C) leads to the formation of small Au tips located at the edges, whose size can be controlled through photo-reduction. When the reaction is carried out at higher temperature (70°C), cation exchange tends to be favored, leading to the formation of the narrow band gap semiconductor Au_2Se .

We also investigate the change in transport properties resulting from gold functionalization. In the presence of gold tips obtained by gold reduction, the conductance is increased by orders of magnitude. To understand the origin of this conduction enhancement, we examine the chemical bonding and the electronic structure using XPS and KPFM measurements. XPS indicates that the gold is present only

under the Au⁰ form and we can exclude the formation of Au₂Se and the correlated band gap reduction as a possible mechanism for the rise of conductance. Upon gold tipping, XPS and KPFM measurements point to a reduction of the energy difference between the Fermi level and the top of the valence band. We discuss why this phenomenon happens (electron charge transfer to gold and Schottky barrier formation, p-doping by substitutional gold atoms) and examine the consequences on the NPL film conductivity. As the electron carrier density is decreased and as we lack further knowledge about hole mobility in CdSe NPLs, we refrain from attributing the overall increase in conductance to an increased conductivity in the p-doped semiconductor. We rather favor the hypothesis that transport actually results from tunnel events between metallic tips and that the semiconductor plays a limited role here.

Acknowledgements

We thank Fausto Sirotti and Mathieu Silly from the Tempo beam-line of synchrotron SOLEIL, who gave us the opportunity to measure the CdSe work function. We also thank Etienne Rochette for help with the syntheses. This work was supported by French state funds managed by the ANR within the Investissements d'Avenir programme under reference ANR-11-IDEX-0004-02, and more specifically within the framework of the Cluster of Excellence MATISSE led by Sorbonne Universités. S.I. and A.O. thanks Agence Nationale de la Recherche (ANR) for funding through grant Nanodose and grant H2DH, respectively.

Supporting information

The supporting information includes details about the NPL material processing and the XPS methodology, in particular, the original procedure we used to eliminate differential charging in these low conductance material. This material is available free of charge *via* the Internet at <http://pubs.acs.org>.
