**ABSTRACT:** Low frequency dynamics has been studied in a CH$_3$NH$_3$PbBr$_3$ hybrid perovskite single crystal by using four different spectroscopy techniques: coherent inelastic neutron, Raman and Brillouin scatterings, and ultrasound measurements. Sound velocities were measured over five decades in energy to yield the complete set of elastic constants in a hybrid halide perovskite crystal in the pseudocubic plastic phase. The $C_{44}$ shear elastic constant is very small, leading to a particularly low resistance to shear stress. Brillouin scattering has been used to study the relaxation dynamics of methylammonium cations and to evidence translation–rotation coupling associated with the cubic to tetragonal phase transition at $T_c \approx 230$ K. Low frequency and highly damped optical phonons observed using both Raman and inelastic neutron below 18 meV, do not present softening close to $T_c$. The critical dynamics at $T_c \approx 230$ K is compatible with an order–disorder character, dominated by relaxational motions of the molecules.

During the past few years, hybrid halide perovskites have been intensively studied as promising materials for photovoltaic and optoelectronic applications. Though most experimental studies have been performed on MAPbX$_3$ compounds, where MA = CH$_3$NH$_3^+$ is the methylammonium cation and X = I, Br, or Cl an halogen atom, the halide perovskite bulk and alloy compounds are nowadays also based on the formamidinium (FA = HC(NH$_2$)$_2^+$) and cesium (Cs+) cations to enhance photoconversion or light emission efficiencies.\textsuperscript{9–11} However, optical absorption and charge carrier mobilities are among the stumbling blocks that limit the maximum photocurrent of solar cells. Previous experimental studies have successfully evidenced the influence of the structural properties on the optoelectronic properties of the hybrid halide perovskites, but a comprehensive understanding is still lacking.\textsuperscript{12–15} Besides a few older experimental studies dedicated to the dynamics of the MA cation,\textsuperscript{16–17} a number of experimental and theoretical papers appeared recently addressing the structural and vibrational properties of MAPbX$_3$ compounds.\textsuperscript{18–25} Despite the importance of the macroscopic mechanical properties for material processing, thermal and photostabilities or at the microscopic level for inelastic carrier scattering or exciton screening,\textsuperscript{18,28} to the best of our knowledge very few experimental studies have been reported so far on the acoustic phonons.\textsuperscript{29,30} The technologically important isostructural MAPbI$_3$ and MAPbBr$_3$ hybrid perovskite compounds have a primitive cubic structure at high temperature and undergo a cubic (Pm-3m) to tetragonal (I4/mcm) antiferrodistortive phase transition\textsuperscript{15,31–33} respectively at $T_c \approx 333$ K and $T_c \approx 230$ K (227 K to 233 K according to different experimental studies\textsuperscript{15,31,33} and 231 K in this work). Recent detailed structural X-ray and neutron diffraction investigations indicate highly anisotropic displacement ellipsoids of the halogen ions.\textsuperscript{34} It may correspond to a large damping of low-frequency optical modes associated with in-phase and antiphase rotations of the PbX$_6$ octahedra.\textsuperscript{35–37} This behavior was already observed in the CsPbCl$_3$ bulk crystal by neutron scattering.\textsuperscript{37} It is also unclear whether this strong anharmonicity is at the origin of the structural Pm-3m to I4/mcm phase transition or not. A displacive character of this structural transition would correspond to an anomalous behavior of the frequency and damping of the critical optical phonon mode at the phase transition temperature $T_c$. For instance, the so-called "lattice melting" phenomenon observed around the ferroelastic structural phase transition of Na$_2$CO$_3$,\textsuperscript{38} is also related to a strong anharmonicity of atomic displacements. It leads to large lattice strain and vanishing elastic constants at $T_c$. Although the same behavior is not expected at $T_c$ in MAPbX$_3$ compounds because the Pm-3m to I4/mcm transition is still lacking.\textsuperscript{12}

phase transition is not ferroelastic, a linear—quadratic coupling between the transition order-parameter and the strain was predicted.16 This may partially affect the elastic constants.

The stochastic reorientational motion of the MA cation at high temperature has been studied by various experimental and theoretical approaches.36,39—41 Theory predicts linear translation-rotation coupling that leads to a softening of the perovskite lattice as well as a damping of the sound waves propagating in the crystal.36 Correlated tumbling of the MA cations are also expected to play a role in the mechanism of the Pm-3m to I4/mcm phase transition. A pseudospin variable related to such stochastic motions may be related to the order parameter and rather suggests an order—disorder character of the structural instability at $T_c$.36 Moreover, analogy with classical plastic crystals at high temperature has prompted the prediction of an orientational glassy state at low temperature.36 Indeed, recent experimental investigations combining dielectric measurements and calorimetry are consistent with this hypothesis.42

The aim of this work is to provide a detailed analysis of low energy structural excitations in the high temperature plastic phase, by combining coherent neutron, Raman, and Brillouin scattering (BS), as well as ultrasonic (US) measurements. Using large single crystals of MAPbBr3 offers the unique opportunity to investigate the structural instabilities of the MAPbX3 family. In fact, it provides a RT high symmetric cubic Pm-3m phase, avoiding coexistence of ferroelastic domains and crystal twinning. MAPbBr3 is also particularly suited to common laser sources used for Raman and Brillouin optical spectroscopies dedicated to vibrational properties, thus preventing resonant excitations. Overall, the experimental study shows that strong anharmonicity as well as disordered reorientational motions of the methylammonium cations dominate the spectrum of low energy structural excitations in MAPbX3 compounds. The results are consistent with an order—disorder character of the cubic to tetragonal structural phase transition, which affects the elastic properties through a strong translation-rotation coupling. Then, the acoustic phonons have been studied over five decades in energy and a complete set of elastic constants has been determined. The final section gives some perspectives.

At high temperature, experimental crystal structures of HOP do not reveal strictly ordered and symmetric phases as a consequence of molecular symmetry of the organic cations that do not fit the site symmetry of the lattice. Related dynamical disorder was already analyzed a long time ago by various experimental techniques.15—17 Nevertheless, in these studies, their reference high temperature phase can be taken as being the Pm-3n cubic phase, for example, that of CsPbX3 ($Z = 1$).

Figure 1a represents the real space 3D view of the Pm-3m crystal structure of metal—halide AIP or HOP of general formulas AMX3, where A is an inorganic or an organic cation such as CH3NH3+ M a metal, and X an halogen. In HOP, the CH3NH3+ cation is located at the center of the cube with an averaged position sketched by the brown ball. (b) Reciprocal space 3D view showing the first Brillouin zone (BZ) of the Pm-3m space group. Points of high symmetry in the cubic BZ are indicated by conventional letters: Γ denotes the origin of the BZ; X is the center of a square face at the BZ boundary; $M\left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)$ is a center of a cube edge and $R\left(\frac{1}{2}, \frac{1}{2}, \frac{1}{2}\right)$ corresponds to a vertex of the cube.

$^a$V$_{\text{LA}}$ (Figure S1). $^b$V$_{\text{TA1}}$ (Figure 2a) and V$_{\text{TA2}}$. $^c$BS. $^d$INS. $^e$US. $^f$The experimental values of the $C_{11}$, $C_{12}$, and $C_{44}$ elastic constants for MAPbBr$_3$ in the $Pm-3m$ cubic phase are reported. Sound velocities and elastic constants are respectively given in m/s$^{-1}$ and GPa. $K$, $E$, and $G$ correspond to the bulk, Young, and shear elastic moduli, respectively. The largest relative error is obtained for the $C_{12}$ value, which depends on the measurements of both $V_{\text{LA}}$ and $V_{\text{TA2}}$ (see SI). For instance, considering $C_{11} = 32$ GPa (INS) instead of $35.9$ (BS) leads to $C_{12} = 7.7$ GPa.

These values reveal anisotropic crystal properties that are comparable but significantly lower than predicted values ($C_{11,\text{DFT}} = 47.2$, $C_{44,\text{DFT}} = 8.1$, and $C_{12,\text{DFT}} = 10.2$ GPa), but in good agreement with recent ultrasonic measurements. However, DFT predictions are based on a pseudocubic cell with a fixed orientation of the MA cation. Thus, the $Pm-3m$ lattice symmetry is automatically broken, leading to a polar space group. While the elastic stability of the computed structure has already been checked, nothing is reported concerning the stability of the structure with respect to the lattice distortions related to the optical modes. Indeed, these modes are expected to induce the low temperature structural phase transitions. However, the DFT computation, which does not contain entropy contribution, does not account for the stochastic relaxational rotation of the MA cation which leads to the high temperature softening of the elastic properties via the coupling of acoustic phonons to pseudospin elastic quadrupoles (vide infra).$^{36}$ The Zener parameter $A = 2C_{44}/(C_{11} - C_{12})$ characterizes the deviation from elastic isotropy ($A = 1$) in a cubic crystal. The experimental value at RT for MAPbBr$_3$, $A = 0.32$, is small and very different from those reported for conventional oxide perovskites, about 1.1, 1.6, and 1.3 for SrTiO$_3$, BaTiO$_3$, and PbTiO$_3$, respectively.$^{37}$

Mechanical engineers often describe elastic properties by the Young modulus $E$, the Poisson ratio $\nu$ and the shear elastic modulus $G$. Since cubic structures are not elastically isotropic, these elastic properties depend on strain orientation. An experimental study of mechanical properties based on nanoindentation has been performed on CH$_3$NH$_3$PbI$_3$, CH$_3$NH$_3$PbBr$_3$, and CsPbBr$_3$. This study reports a Young modulus along the [100] direction of $E_{[100]} = 19.6$ GPa, whereas the calculated value from the elastic constants (Table 1) is $E_{[100]} = C_{11} - 2C_{12}/(C_{11} + C_{12}) = 30.2$ GPa. However, the other extreme Young modulus value along [111] is $E_{[111]} = 3C_{44}(C_{11} + 2C_{12})/(C_{11} + 2C_{12} + C_{44}) = 11$ GPa (Table 1). A first hypothesis for the discrepancy between both measurements of $E_{[100]}$ may be related to the fact that the nanoindentation technique may lead to an average over Young modulus values close to the [100] direction. A second hypothesis relies on the fact that nanoindentation can be considered as a quasistatic measurement, whereas BS probes...
the elastic properties in the 5–25 GHz frequency range, that is, in the 20–100 μeV range (Figure 3). Therefore, the difference between the two experimental $E_{1(100)}$ values is likely to result from a frequency dependent softening related to translation-rotation coupling (vide infra). This is usually referred to as the difference between the isothermal (low-frequency) and adiabatic (high-frequency) behaviors. On the contrary, the bulk modulus $K = (C_{11} + 2C_{12})/3$ is 19.7 GPa (Table 1) agrees well for both methods yielding a value of about 16 GPa by nanoindentation. This is also consistent with US measurements yielding the same LA velocity as BS at much lower energy (0.031 μeV).

The difference between the isothermal and adiabatic values of the Young moduli can thus be ascribed mostly to the isothermal and adiabatic $C_{44}$ elastic constants, which does not appear in the expression of the bulk modulus and the LA velocity along the [100] direction (see Supporting Information). A difference between the nanoindentation and the present Brillouin scattering studies exists for the shear modulus, which equals $G_{44} \approx 4$ GPa for a $(x-z)$ shear and $(C_{11} − C_{12})/2 \approx 12$ GPa for a $(x-y)$ shear according to our measurements, whereas an intermediate shear modulus value of 7.6 GPa was deduced from the indentation experiment.\(^{47}\) However, the comparison is less relevant as the nanoindentation shear modulus was deduced by combining, within the isotropic approximation, the experimental Young modulus (19.6 GPa) and a DFT computation of the Poisson’s ratio (0.29).

The softening of the elastic properties induced by the translation–rotation coupling may be associated with specific directions of the reciprocal space, as indicated by the INS measurements, which show a clear difference between the LA and TA measurements close to the (200) and (111), (011) Bragg reflections. Finally, let us mention that the formation of small polarons, likely responsible for part of the efficiency drop in the 20\(^{\circ}\) C–170\(^{\circ}\) C range, is supposed to be related to the simultaneous softening of phonons with pure antiphase and in-phase rotations of PbBr\(_6\) octahedra (Table 2, Figure 1). These two IR (irreducible representation) may correspond to the simultaneous softening of phonons with pure antiphase and in-phase rotations of PbBr\(_6\) octahedra respectively, or also pseudospin critical fluctuations (Table 3). The $M'_4$ order parameter may thus be associated with an order–disorder character of the transition or a soft phonon like in CsPbCl\(_3\).\(^{37}\)

“The contributions from each atomic or molecular site (1a, 1b, 3d) are indicated. The symmetric (+) and antisymmetric (−) $IR$ correspond to non-polar and polar phonon modes, respectively.

More, a linear-quadratic coupling between the strain tensor components and the $R'_4$ symmetry around the cubic Pm-3m to tetragonal $I/4/mcm$ phase transition is predicted from a symmetry analysis.\(^{36}\) At lower temperature, MAPbBr\(_3\) exhibits a first order and reconstructive structural phase transition from the tetragonal $I/4/mcm$ phase to a $Pnma$ orthorhombic phase (see Swainson et al. for instance).\(^{31}\) An intermediate phase between 148.8 K and 154 K was also reported by Onoda and co-workers\(^{16}\) between the two phases. The structural instability, which leads to the low temperature $Pnma$ phase, is supposed to be related to the simultaneous condensation of order parameters with $M'_4$ and $R'_4$ symmetries (Table 2, Figure 1). These two $IR$ (irreducible representation) may correspond to the simultaneous softening of phonons with pure antiphase and in-phase rotations of PbBr\(_6\) octahedra respectively, or also pseudospin critical fluctuations (Table 3). The $M'_4$ order parameter may thus be associated with an order–disorder character of the transition or a soft phonon like in CsPbCl\(_3\).\(^{37}\) 

Coherent INS experiments were thus performed on optical phonons close to the $R$ (Figure 4) and $M$ (Figure S6) points of the BZ. These experiments did not reveal any measurable change of the optical phonons as a function of the temperature in the cubic and tetragonal phases down to 180 K. As shown on Figure 4, the spectrum measured at $\left(\frac{3}{2}, \frac{3}{2}, \frac{3}{2}\right)$ exhibits peaky features in the [6–17 meV] range, consistent with our available Raman scattering data (vide infra) in the low energy range (a similar measurement was performed at $\left(\frac{3}{2}, \frac{3}{2}, \frac{3}{2}\right)$ and $\left(\frac{1}{2}, \frac{3}{2}, \frac{3}{2}\right)$ positions). Three optical phonons in this energy range are fitted by damped harmonic oscillator (DHO) functions and a background (BG) is added. Fitting parameters are given in the SI. The comparison between the INS intensities at $\left(\frac{3}{2}, \frac{3}{2}, \frac{3}{2}\right)$ and $\left(\frac{1}{2}, \frac{3}{2}, \frac{3}{2}\right)$ shows an enhancement of the INS structure factors between 0 and 10 meV (Figure 4 inset). In order to understand the origin of this low energy feature, it is interesting to recall that a low energy phonon mode (5 meV) was reported by INS in the orthorhombic phase by Swainson et al.\(^{33}\) This phonon line corresponds to rotations of the PbBr\(_6\) octahedra and undergoes a progressive softening when increasing the temperature toward the orthorhombic to tetragonal transition at 150 K. However, the sharp, harmonic modes in the orthorhombic phase ($Pnma$) are replaced in the tetragonal phase ($I/4/mcm$) by quasistatic fluctuations extending up to high energies at 200 K. A soft phonon line is usually expected in the high temperature phase for a continuous phase transition. However, the orthorhombic to tetragonal phase transition in MAPbX\(_3\) compounds does not fall into this
Figure 4. Low energy optical phonon spectra measured by inelastic neutron scattering in the cubic phase of CH$_3$NH$_3$PbBr$_3$ ($T = 280$ K) at various $R$ points of the BZ reveal two different features: the spectrum measured at the ($\frac{1}{2}, \frac{3}{2}, \frac{3}{2}$) point exhibits a quasi-elastic (QE) contribution and three optical phonons (main plot). Optical phonons are fitted by damped harmonic oscillator (DHO) functions and a background (BG) is added. Fitting parameters are given in the SI. The inset shows difference between spectra measured at ($\frac{1}{2}, \frac{3}{2}, \frac{3}{2}$) and ($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$), highlighting the enhancement of the ($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$) intensity at low energy. A third measurement carried out at ($\frac{1}{2}, \frac{3}{2}, \frac{3}{2}$) did not reveal any enhancement.

category, because it is reconstructive, without group—subgroup relation between the I4/mcm and Pnma space groups. The orthorhombic to tetragonal transition at 150 K in MAPbBr$_3$ represents thus a case where a displacive PbBr$_6$ octahedra dynamics is replace by an order—disorder MA dynamics, at high temperature. Indeed, our observations around the tetragonal to cubic phase transition do not show any indications of phonon mode softening. Thus, it is consistent with a purely order—disorder character of the tetragonal to cubic phase transition. More, previous experimental and theoretical determinations of neutron scattering structure factors for R$_{3}^{+}$ PbCl$_6$ octahedra soft phonons in CsPbCl$_3$ show similar values at the ($\frac{3}{2}, \frac{1}{2}, \frac{1}{2}$) and ($\frac{1}{2}, \frac{3}{2}, \frac{3}{2}$) positions contrary to the present results for MAPbBr$_3$ (Figure 4). The low energy feature measured at the ($\frac{1}{2}, \frac{3}{2}, \frac{3}{2}$) position (Figure 4 inset) thus probably corresponds to the additional critical quasistatic fluctuations reported by Swainson et al., between 0 and 10 meV in the tetragonal phase. No precise indication about the localization in reciprocal space was given in this reference, but the associate Q vector interval corresponds roughly to the one of the present study $Q < 5$ Å$^{-1}$. Low energy optical phonon spectra measured by INS in the cubic phase of CH$_3$NH$_3$PbBr$_3$ ($T = 245$ K) at the $M$ point (Figure S6 ($\frac{3}{2}, \frac{3}{2}, \frac{3}{2}$)) also show a broad quasi-elastic contribution between 0 and 10 meV, whereas M$^{+}$ PbX$_6$ soft phonons should exhibit a structure factor equal to zero. This observation is consistent with the prediction of the simultaneous condensations of M$^{+}$ and R$^{+}$ order parameters in the orthorhombic Pnma phase, both having an order—disorder pretransitional dynamics in the high temperature phases of MAPbX$_3$ compounds contrary to CsPbCl$_3$.

Low energy structural excitations in MAPbBr$_3$ single crystals were also explored at RT using Raman scattering. At first sight, classical symmetry-based selection rules for Raman scattering in Pm-3m perovskite crystals lead to the prediction of totally forbidden optical activity for the polar optical lattice phonons at $I$ point when the MA$^{+}$ cation is replaced by its center of mass (Table 3). Raman activity is thus only expected for high frequency internal modes of the MA$^{+}$ cation. However, it is known that Raman scattering signatures may be obtained at very low frequency in plastic crystals, due to symmetry allowed contributions associated with stochastic molecular relaxational motions. Moreover, we cannot rule out the influence of the large anharmonicity of the iodide motions on the breaking of the Raman scattering selection rules. Such signatures recorded experimentally are clearly visible in Figure 5. The three independent Raman scattering spectra $A_{1g}$ ($I_{x}^{\pm}$), $E_{g}$ ($I_{y}^{\pm}$), and $T_{2g}$ ($I_{z}^{\pm}$) were obtained at RT by measuring parallel ($VV$) and crossed ($VH$) polarized spectra in two different scattering geometries. The symmetry analysis (vide infra) shows that it is possible to compare and calibrate the sum of both $I_{VV}$ and $I_{VH}$ spectra for the two scattering geometries (Figure 5-a). This enables to determine accurately the three independent spectra

Figure 5. Low energy optical phonon spectra measured by Raman scattering in the cubic phase of CH$_3$NH$_3$PbBr$_3$ at room temperature. (a) Total contribution of parallel ($I_{VV}$) and crossed ($I_{VH}$) polarized intensities with propagation directions along [001] and incoming polarization along [100] or [110]. (b) Raman spectra of $T_{2g}$, $E_{g}$ and $A_{1g}$ modes. Inset: zoom to highlight an $A_{1g}$ optical mode near 40 meV.
The A1g spectrum largely dominates, while Eg and T2g spectra reveal comparable intensities. All, the three spectra show broad bands and the A1g spectrum is superimposed on an intense quasi-elastic component. This observation is consistent with previous theoretical modeling of tumbling relaxational motions of cations in MAPbX3, using symmetry-adapted discrete pseudo-spins or continuous rotators.36,39 Indeed, relaxational modes include polar modes, with contributions to the lattice dielectric constants, but also nonpolar modes (elastic multipoles) with A1g (∊5'), Eg (∊5'), and T2g (∊5') symmetries. The inset highlights the high frequency part of the measured spectra showing an A1g optical mode at about 40 meV. This mode may be tentatively assigned to a symmetric internal mode of the CH3NH3 cation.

Temperature-dependent Brillouin backscattering measurements allow probing the coupling between low energy relaxational modes and phonons at lower energies than Raman scattering (Figure 5-b). The LA phonon mode exhibits an anomalous increase of its damping as the temperature is lowered. The TA phonon mode is very weak due to restrictive normal incidence conditions when performing the low temperature measurements, as compared to the setup used at RT (Figure 3).

Figure 6. Brillouin scattering spectra of MAPbBr3 for normal incidence above (T = 313 K) and very close to the transition temperature (238 K). The LA phonon mode exhibits an anomalous increase of its damping as the temperature is lowered. The TA phonon mode is very weak due to restrictive normal incidence conditions when performing the low temperature measurements, as compared to the setup used at RT (Figure 3).

Figure 7. Frequency widths (HWHM) of the LQE and CP quasi-elastic peaks as a function of the temperature. Low temperature CP widths above the transition are fitted using an Arrhenius law, allowing extrapolation of high temperature values (red crosses).

where χ(T)(E) is the imaginary part of the coupled optical susceptibility (see Supporting Information). As shown in Figure S7, a significant lowering of the LA Brillouin shift is observed after correction of the coupling with CP. Moreover, the coupling strength between the LA phonon and the central relaxational mode is highest at the phase transition temperature (Figure S8). Both observations are consistent with a linear–quadratic coupling between the strain and the order parameter of the phase transition, which exhibit an order–disorder character.

This picture is further illustrated in Figure 7, where the widths of the CP and the LQE are reported as a function of the temperature. The evolution of the two different widths seems to be in line with the scenario proposed by Chen al for CH3NH3PbI3.40 They describe a rotational model of the CH3NH3+ molecule, associated with two relaxational motions, the slowest one being related to the tumbling of the C–N axis and the fastest one with the rotation around the same axis. Therefore, the LQE observed in the present BS experiments on MAPbBr3 may be attributed to the fast motion of the hydrogen atoms around the C–N axis, whereas the CP can be tentatively assigned to the tumbling motion of the cations. Then, the characteristic relaxation times can be calculated from

\[ \Gamma = \frac{k}{h} = \frac{\hbar}{\tau} \]

where \( k \) is the Boltzmann constant, \( h \) is Planck's constant, and \( \tau \) is the relaxation time in ps. The corresponding relaxation time at \( T \), deduced from the present study on MAPbBr3 (Figure 7) is about 28 ps (CP). In MAPbI3, the relaxation times reported by the INS study being equal to about 3 ps for the CP at \( T = 330 \) K.40 In MAPbBr3, the CP obtained by BS exhibits an anomaly around \( T_c \) in the [220–240 K] temperature range (Figure 7). We may notice that the CP obtained in MAPbI3 by INS is also exhibiting a discontinuity at the cubic to tetragonal phase transition, although a precise comparison with the present work is difficult since the INS study displays very few experimental points in the same temperature range close to \( T_c \).40 The CP anomalies close to \( T_c \) in MAPbX3 compounds should be investigated more precisely in the future using other experimental techniques.

The relaxation times reported for the two compounds using various techniques are gathered in Table 4. The tumbling of the C–N axis is frozen in the orthorhombic Pnma phase of MAPbI3, whereas the motion of the hydrogen atoms around...

Coherent INS experiment has been performed using the triple-axis spectrometer 4F1 located on a cold-neutron source at the reactor Orphée (Laboratoire Léon Brillouin, CEA-Saclay). The incident and scattered beams were focused by a pyrolytic graphite (002) double-monochromator and analyzer, respectively. The collimation conditions were open. The final neutron wave vector was held fixed at \(k_l = 1.55 \text{ Å}^{-1}\). A beryllium filter cooled with liquid nitrogen was placed after the sample to remove high-order neutrons from the beam. The resolution function was of the order of 0.2 meV. Here, the sample is protonated, yielding a large background due to the incoherent neutron cross section of hydrogen. The sample was mounted on a close-cycle refrigerator installed on the spectrometer sample table, ensuring temperature stability less than 0.1 K. The sample was mounted in a scattering plane such that reciprocal directions \((1,0,0)\) and \((0,1,1)\) were within the horizontal plane.

We quote the wave-vector \(Q = (H,K,L)\) in units of cubic lattice vector \(a^* = 2\pi/a\), where \(a\) is the lattice parameter (\(a = 5.91 \text{ Å}\) and \(a^* \approx 1.06 \text{ Å}^{-1}\) at RT). Bragg reflections of the RT cubic phase \(Q = (H,K,L)\) are then accessible. This has been chosen in order to reach the superlattice reflections appearing in both the tetragonal and orthorhombic low temperature phases, which are occurring at the \(M(\frac{1}{2}, \frac{1}{2}, 0)\) and \(R(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})\) or equivalents points.

Ultrasonic time-domain reflectometry measurements have been carried out at RT using a longitudinal probe at 7.46 MHz. A smaller single crystal (\(\sim 0.2 \text{ cm}^3\)) was carefully chosen in order to yield a \((001)\) flat surface with a crystal thickness equal to 3 mm. A thin (<0.1 mm) gel layer was used between the probe and the crystal in order to ensure a maximum transmission and reflection of the ultrasonic pulse.

The polarized Raman scattering spectra covering the frequency range from 7 to 358 cm\(^{-1}\) with a resolution of about 2 cm\(^{-1}\) (full width at half-maximum) were obtained on a triple monochromator Jobin Yvon T64000 spectrometer equipped with a liquid-nitrogen-cooled silicon CCD detector. A linearly polarized diode laser emitting at 660 nm was used to excite the sample and the scattered light was collected through a 50X objective in the backscattering configuration. The laser power impinging the sample with a spot diameter of 3 mm was kept below 1 mW to avoid heating effects. An analyzer was used to select the outgoing polarization, followed by a rotating half-wave plate to maintain a vertical polarization at the entrance of the spectrometer. The polarization-dependent transmission of the collecting optics was calibrated using the known depolarization ratio of the \(T_{2g}\) Raman mode measured in backscattering on a [111] silicon plate: \(I_{01}/I_{CV} = 2/3\). The two MAPbBr₃ samples used for the Raman scattering experiment were single-crystal plates (\(\sim 4 \times 4 \times 1 \text{ mm}^3\)) with the surface oriented perpendicularly to the [001]-type cubic direction. Setting the polarization of the incoming beam along [100] and measuring parallel and crossed polarized intensities of the outgoing light leads to the first two spectra \(S_1\) and \(S_2\):

\[
S_1 = A_{1g} + 4E_{g}Z(X, X)Z
\]

\[
S_2 = T_{2g}Z(X, Y)Z
\]

A rotation of the incoming beam polarization along [110] gives the other two spectra \(S_3\) and \(S_4\):

\[
S_3 = A_{1g} + E_{g} + T_{2g}Z(X + Y, X + Y)Z
\]

\[
S_4 = T_{2g}Z(X, Y)Z
\]

\[
S_5 = A_{1g} + E_{g} + T_{2g}Z(X + Y, X + Y)Z
\]

The C–N axis is still effective. A further slowing down of the two relaxation modes may be inferred below 230 K for MAPbBr₃ (Figure 7). Unfortunately, a complete study around the tetragonal to orthorhombic phase transition at 150 K was not possible due to the presence of multiple strained domains, and thus multiple acoustic phonon lines below \(T = 200 \text{ K}\).

Through combined neutron, Brillouin and Ultra Sound scattering measurements, we were able to measure for the first time the transverse and longitudinal sound velocities of CH₃NH₃PbBr₃ perovskite single crystals allowing RT evaluation of the three cubic elastic constants. It reveals a very low value of the \(C_{44}\) shear constant. A further softening is observed by Brillouin scattering close to the cubic to tetragonal phase transition, by a low energy coupling between the LA phonon mode and a CP. This CP is attributed to a relaxation mode of the \(\text{CH}_3\text{NH}_3^{+}\) molecule (tumbling around the C–N axis), which is consistent with an order–disorder character of the structural phase transition. Broad quasi-elastic excitations and low energy optical phonons were also observed for the first time using INS, confirming the large anharmonicity of the perovskite lattice modes. These optical modes do not exhibit a displacive behavior in the cubic and tetragonal phases, but Raman scattering, INS and Brillouin scattering are compatible with an order–disorder character related to the stochastic relaxation motions of the \(\text{MA}^+\) cations. This disorder leads to a breaking of the Raman scattering selection rules in the high temperature phase, characteristic of a plastic crystal phase.

#### EXPERIMENTAL METHODS

Various single crystals of MAPbBr₃ have been synthesized, purified and grown according to Saidaminov et al. with sizes up to \(\sim 1 \text{ cm}^3\) (see Supporting Information). Concerning the Brillouin scattering experiments, spectra were recorded at 647.1 nm by using a krypton ion laser and a tandem of Fabry–Perot interferometers where each interferometer is triple-passed giving a contrast larger than \(10^{11}\). Different free spectral ranges between 10 cm\(^{-1}\) (1 cm\(^{-1}\) = 30 GHz, 8 cm\(^{-1}\) = 1 meV) and 1 cm\(^{-1}\) have been used in order to give a full description of the low-frequency spectra. The advantage of this tandem of interferometers over the single one (see for instance Sandercock) is that it removes the periodicity of the interferogram allowing the observation of broad and narrow components in the same spectrum without any confusion due to order overlapping. The polarization of the incident light was rotated by a half-wave plate and filtered by a Glan prism, whereas the scattered beam was not analyzed.
It is interesting to note that for both sets of geometry sums of parallel and crossed polarized spectra are expected to be identical, that is, \( S_p + S_c = S_{pc} + S_{cp} = A_0 + 4E_p + T_{c0} \). We used this property to obtain the intensity scale factor between the two scattering geometries.
