A B S T R A C T

A dual experimental-numerical approach was carried out to estimate thermal cycles and resulting fusion depths obtained during the selective laser sintering (SLS) of two polymers: PA12 and PEKK. The validation of thermal cycles was obtained by considering fusion depths on single layers for different experimental conditions and temperature measurements with IR thermal camera. It was shown that a simple Beer-Lambert's heat deposit equation incorporating an extinction coefficient determined experimentally and an efficiency ratio including both laser absorption and diffusion in the powder bed were sufficient for determining accurately fusion depths, and heat cycles for the two polymers. This allowed determining optimum process conditions for manufacturing additive layers on a specifically-designed SLS set-up.

1. Introduction

The selective laser sintering (SLS) or selective laser melting (SLM) technique has now become a viable technique for producing parts of short series of complex shapes, not only on metals but also on polymers as shown by Kruth et al. (2007), Pham et al. (2008), or Goodridge et al. (2012). Many industrial machines already exist that allow fabricating solid thermoplastic polymer components, either on rather low fusion temperature polymers like PA6 (Pham et al., 2008) and PA12 (Dupin, 2012) polyamides, or amorphous polymers (Childs et al., 1999). Other works have focused on more technical polymers such as PEEK Schmidt et al. (2007) or PEKK (Dumoulin, 2014). When applied to semi-crystalline polymer materials, the SLS technique requires a high temperature maintain at T_0 level, comprised between the crystallization temperature start T_c^s and the melting temperature start T_m^s . Too low temperatures (below T_c^s) promote thermal shrinkage during crystallization and layer deformation, which is unacceptable for additive manufacturing. In turn, a small work temperature range WTR ($\Delta T = T_m^s - T_c^s$) can be a very limiting factor for a given polymer, because a precise control of the temperature becomes a critical point (Fig. 1). Crystallization rates should also be maintained at a low level during the whole process, and especially during the spreading stages, in order to limit extensive distortion that prevents stable layer addition. Other critical

aspects of the SLS process come from the thermo-physical properties of polymers, especially their high viscosity (nearly 10^6 times the viscosity of metals) that limits polymer flow, and resulting densification rates. However, as reminded by (Kruth et al., 2007), the reason why specific polymers such as polyamides PA sinter well compared with other polymers is not fully clear yet, even if low viscosities and molecular weights are usually considered as beneficial for enhancing powder beds densification. Although the SLS process has many industrial applications, the physical processes involved during the laser-polymer powder layer interaction are not well described because industrial set-ups do not favor physical instrumentations. Consequently, there is a real need for understanding the basic phenomena involved in the SLS process, considering more simple and opened set-ups than industrial machines. This includes the determination of laser-polymer layer coupling (absorptivity, extinction coefficients), temperature profiles $T = f(t)$ on molten layers, and densification kinetics.

Previous publications have proposed macroscopic thermal numerical models for the SLM or SLS process like the 3D SLS model by Dong et al. (2009), the 3D SLM model of Hussein et al. (2013), or more microscopic models considering powder densification at a local scale like the recent work by (Defauchy, 2013). However, most of these numerical works, and especially those carried out at a macro-scale or meso-scale on commercial codes did not systematically validate their results with experimental data, and most of all did not characterize laser-powder bed interaction. Recently, Franco and Romoli (2012) have addressed laser-polymer powder interaction on single sintered lines, with the objective of analyzing

x_{scale}	coefficient of the heaviside step function (m)
ΔH_m	latent heat of melting (J/kg)
α	extinction coefficient of Beer–Lambert's equation (m^{-1})
Δh	layer thickness (m)
δ	porosity ratio
ε	emissivity
ρ	density (kg/m^3)
σ	Stefan–Boltzmann coefficient ($=5.67 \times 10^{-8} \text{ W/m}^2/\text{K}^4$)
τ	laser pulse duration (s)

experimentally the laser energy consumption through the determination of geometrical features of fusion lines. However, they did not consider a combined numerical and experimental approach.

In another rather pioneer work by (Tolochko et al., 2000), the determination of normal spectra absorbance of a large range of

Fig. 1. DSC profile of a semi-crystalline polymer (from Defauchy, 2013)—On PA12, the rather large WTR (≈ 29 K) favors the SLS process.

metals and polymer powders under Nd:YAG or CO_2 laser irradiation was investigated, but without considering in-depth transmission aspects.

In this context the current work, carried out in the frame of a French national research project (FUI Fadiplast) was focused on three objectives: (1) to develop a small SLS prototype with dedicated diagnostics to carry out instrumented SLS tests, (2) to investigate laser–powder bed interaction, (3) to carry out numerical simulations to validate laser-material coupling and address the influence of process parameters on the thermal cycles experienced by surface layers. Two polymers have been investigated: a PA12 polyamide, and a more technical PEKK (polyetherketoneketone) with different thermo-physical properties (Table 1).

2. Materials, experimental, and numerical conditions

2.1. The polymers

Two semi-crystalline polymers have been investigated: a polyamide (PA12) and a PEKK, which differ mainly by their melting and crystallization temperatures (Table 1), resulting in smaller WTR for PEKK (≈ 29 K) than for PA12 (≈ 17 K), and by their viscosity η (higher for PEKK). Moreover, the PEKK is expected to be usable at much higher temperatures (up to 570 K) than the PA12 (320 K). Powder grain diameters were in-between 30 and 70 μm for the PA12 polyamide and in-between 10 and 90 μm for the PEKK (average value $D_{50} = 50$ μm for both), with a more spherical shape for the PA12 powders than for the PEKK.

2.2. The experimental SLS set-up

A specific SLS system was fully designed and manufactured in order to investigate basic phenomena involved during the selective laser sintering of polymers. This system is composed (Figs. 2 and 3) of:

- (1) Two plateaus (a manufacturing plateau, and a powder feeding plateau), with a stainless steel knife as layering device, allowing to spread layer thickness of less than $\Delta h = 0.1$ mm height with a ± 0.005 mm accuracy;
- (2) Two heating systems: a resistive-heating (Joule's effect) positioned below the two plateaus, and a radiant system composed of six high power infra-red (IR) radiant lights operating in the 0.7–2 μm wavelength range, and located on top of the building plateau. This heating system is different from those available in industrial machines, but allows nearly identical thermal rise and fall;
- (3) A laser system composed of a 50 W CO_2 laser (ULR40, Continental) working in pulse width modulation mode (PWM: see Section 3.3.1) at 5 kHz frequency at $\lambda = 10.6$ μm , a beam expander, a scanning head, and a 300 mm focal f-theta lens;
- (4) Different diagnostics: a pyrometer operating in the 8–14 μm wavelength range, to record the temperature of the powder layer on a 5 mm diameter area, a SC4000 FLIR thermal camera with a 320×240 pixels sensor, working in the 2–4 μm wavelength range, and a fast camera (Pixel Link) with a 200 Hz maximum frequency rate.

A SLS experiment can be summarized as follows: (1) a powder layer (30–80 μm thickness) is spread on the building plateau at average spreading temperatures of 373 K (for PA12) and 373–473 K (for PEKK), (2) after a few tens of seconds of IR heating, the powder layer surface reaches its optimum processing temperature T_0 (controlled by the pyrometer) comprised within the WTR, and the CO_2

laser irradiates and melts a given powder thickness, (3) another layer is spread.

During all the multi-layer SLS process, the temperature of the building plateau is controlled by a PID in order to be maintained within the WTR. The experimental system and its laser marking software allow building rather simple shapes, but with rather long time durations (a few minutes) between subsequent layers. However, it allows positioning dedicated instrumentation around laser-powder interaction.

2.3. Numerical conditions

3D Numerical calculations of laser-heating were carried out on a laptop computer equipped with a four-core processor of 1.6 GHz frequency and 1600 MHz random access memory, using COMSOL

Multiphysics™ 4.2 software, and more specifically its thermal module. The meshed volume considered for the thermal simulation was a 5 mm × 4 mm × 1 mm body (Fig. 4). Linear hexahedral elements were considered, with a mesh refinement in the laser path.

The heat equation was numerically solved in transient conditions Eq. (1), with heat losses considered in terms of natural convection and radiative losses. In the equation of heat capacity Eq. (2), the energy of solid-liquid change ΔH_m is distributed, through a Gaussian law (Bonaccina et al., 1973), between the fusion start T_{ms} and fusion finish T_{mf} temperatures ($\Delta T = T_{mf} - T_{ms}$). Last, the laser heat deposit Q_v was considered as a volume input, following a Beer's lambert attenuation law (see Section 3.1.2).

$$\rho C_p^* \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + Q_v \quad (1)$$

Fig. 3. Simplified scheme of the SLS device.

Fig. 4. 3D finite element model implemented for transient thermal calculations on COMSOL Multiphysics™.

where, k is the thermal conductivity assumed to be constant with temperature, Q_v the heat source (W m^{-3}), and C_p^* the modified heat capacity integrating solid-liquid phase transformation as follows:

$$C_p^* = C_p(T) + \frac{\Delta H_m}{\sqrt{\pi(T_{mf} - T_{ms})^2}} \exp\left(-\frac{(T - T_{ms})^2}{(T_{mf} - T_{ms})^2}\right) \quad (2)$$

where, T_m is the temperature at the melting point (K), T_{ms} and T_{mf} (K) the temperatures of fusion start and finish respectively, ΔH_m the enthalpy heat of fusion, $C_p(T)$ is considered as a constant value.

The thermal conductivity k of the powder bed was simply taken into account by considering a porosity ratio δ as follows Dong et al. (2009):

$$k = k_0(1 - \delta) \quad (3)$$

The tapped powder porosity ratio was estimated to be around 70% ($\delta = 0.70$) for PA12 and 75% ($\delta = 0.75$) for PEKK. This was evaluated considering the change of volume after melting-solidification, and the resulting displacement of the free surface.

Boundary and initial conditions were considered as follows: Initial conditions were applied as a uniform temperature distribution throughout the powder layer prior to laser melting:

$$T(x, y, z, 0) = T_0, \quad (4)$$

With T_0 = initial temperature of the powder bed. As boundary conditions, convective and radiative heat losses were also considered on external surfaces as follows:

$$-n(k \nabla T) = -h(T - T_{ext}) - \varepsilon \sigma (T^4 - T_{ext}^4) \quad (5)$$

With T is the temperature of the powder bed surface, n = normal direction, T_{ext} the initial ambient temperature (373 K for PA12, and 473 K for PEKK), h the natural convection coefficient at powder bed surface = $15 \text{ W m}^{-2} \text{ K}^{-2}$, ε the surface emissivity assumed to be 0.8 for both powders, σ = Stefan-Boltzmann coefficient ($5.67 \cdot 10^{-8} \text{ W m}^{-2} \text{ K}^{-2}$). A continuous flux boundary condition normal to the surface ($-n(k \nabla T) = 0$) was used in the lateral and bottom part of the geometrical model to ensure a thermal continuity to the model.

As no surface deformation (volume shrinkage) was assumed in this model, the calculation of fusion zones was only carried out considering the first molten layer. It has also to be noticed that thermo-physical properties were kept unchanged after melting (no variation of C_p , k , ρ) were considered after fusion).

3. Results

3.1. Experimental analysis of the laser beam/powder coupling

3.1.1. Experimental determination of laser power spatial distribution

During a SLS process, the spatial distribution of CO_2 laser beam power is of rather high importance, while it directly influences local temperatures experienced by powder grains. For instance, considering similar laser power, non-uniform laser distributions, which are usual for CO_2 lasers generate much higher thermal cycles $T = f(t)$ at the center of laser spots, than at the near edges. To estimate the beam profile distribution, the deformation resulting from a local CO_2 laser fusion induced was measured on a dense polymer. Various laser powers were used that confirmed the spatial distribution. Thanks to the measurement with a 2D profilometer of the shape of the resulting fused crater (case of a static 27.5 W- CO_2 laser irradiation in Fig. 5), an analytical function could be proposed for the focused beam profile. The spatial distribution is shown to be near-Gaussian in shape (with a laser radius r_{laser} equal to 120 μm), and the analytical function providing the best fitting with experimental measurement becomes:

$$Q_0 = Kn \frac{P_0}{(\pi r_{\text{laser}}^2)} \exp\left(-n \frac{(x^2 + y^2)}{r_{\text{laser}}^2}\right) \quad (6)$$

where, Q_0 = surface heat flux (W/m^2), $n=4$, r_{laser} (m) = laser radius at $1/e^2 = 120 \mu\text{m}$, P_0 (W) = average laser power, K = adjustable coefficient < 1 integrating reflectivity R and Mie diffusion D factors ($K = (1-R)(1-D)$) of the laser through the powder layer.

3.1.2. Laser power transmission measurements

Once laser beam distribution was characterized, it became important to investigate laser transmission through the powder

Fig. 5. Static CO₂ laser impact at $P_0 = 27.5$ W laser power on a thick polymer foil. Identification of the laser radius and comparison of the experimentally determined fused profile (2D profilometer) with an analytical quasi-Gaussian distribution.

layers to be able to estimate a reliable analytical heat input for numerical calculations.

For this purpose, a specific device was developed, allowing measurement of the transmission of various powder layer thicknesses, in order to determine the power versus depth attenuation law. The experimental set-up is shown in Fig. 6a. The tapped powder layers, with various thickness obtained using thin foils in the lateral part of the set-up, were spread on a 5 mm-thick NaCl window, allowing a 95% transmission of the CO₂ laser beam. Assuming that no transmission difference exists between ambient and pre-heated powder bed, such measurements were useful data for numerical calculations. Results (Fig. 6b) indicate a fast in-depth attenuation of the transmitted laser beam. This attenuation (and in-turn the laser absorption-diffusion in the powder layer) is shown to follow a Beer-Lambert's equation Eq. (7), which is even more pronounced for the PA12 than for the PEKK. This results in a higher extinction coefficient α for PA12 (9000 m^{-1}) than for PEKK (7500 m^{-1}).

$$Q(z) = Q_0 \exp(-\alpha z) \quad (7)$$

where, α is the extinction coefficient and $Q_0(x,y)$ the surface heat deposit (W/m^2)

3.2. Experimental determination of fusion depths

SLS tests were carried out on single layers to determine the evolution of molten depths with experimental parameters. Scanning speeds V in the 0.1 m/s–1 m/s range were considered, together with laser power P_0 in-between 1.7 W and 7 W for both PA12 and PEKK powder layers.

Prior to laser-melting tests, powder layers (5 mm thick to limit thermal gradients) were pre-heated up to a T_0 temperature (440 K on PA12, and 600 K on PEKK) by using thermal resistances and IR radiant light sources ($0.75\text{--}2 \mu\text{m}$). The surface temperature was controlled by an IR pyrometer, and regulated by a PID system, that allows limiting local thermal variations to less than ± 2 K. The thermal gradient on the building plateau was near 10 K between the edges and the center of the powder bed.

For each condition, optical microscopy was used to estimate fusion depths h (Fig. 7), without taking into account non-melted agglomerated particles. The variation of molten depths was shown to follow a linear dependence versus $P_0/V^{0.5}$ on the two powders investigated so far (Fig. 8).

3.3. Numerical simulation of the SLS process

The numerical description of SLS was considered through the following three aspects:

- The analysis of the PWM regime in order to check the ability of a numerical continuous heat deposit to reproduce a pulsed laser irradiation;
- The FE calculation of fusion depths and thermal cycles induced by SLS;
- The influence of layer deposition on thermal stability of the powder bed.

3.3.1. Numerical analysis of the pulse width modulation (PWM) regime

The CO₂ laser used for SLS experiments operates in pulsed regime at $f = 5$ kHz maximum frequency (period $T_{\text{laser}} = 0.2$ ms) and delivers a peak power of $P_{\text{peak}} = 50$ W. Like most of the CO₂ lasers for SLS applications, it adjusts the mean output power P_0 by multiplying a constant output peak power value P_{peak} by a duty cycle value $\text{dc} = \tau f$ (with τ = laser pulse duration, f = pulse frequency) Eq. (8). For instance, a 10% dc is required to obtain a $P_0 = P_{\text{peak}} \cdot \text{dc} = 5$ W value, starting from a 50 W peak power (Fig. 9a). This configuration is known as pulse width modulation (PWM) mode.

In PWM regime, low dc values can promote discontinuous laser melting when the scan speed is higher than a scan speed threshold V_{max} . This V_{max} , which enables an overlap between laser spots (Fig. 9b), was calculated by Eq. (9). Considering an average power $P_0 = 5$ W and a laser radius $r_{\text{laser}} = 125 \mu\text{m}$, a $V_{\text{max}} = 1.56$ m/s was found. Above V_{max} , laser impacts do not intersect at all.

$$P_0 = P_{\text{peak}} \frac{\tau}{T} = P_{\text{peak}} \tau f \quad (8)$$

$$V_{\text{max}} = \frac{2r_{\text{laser}}}{(T_{\text{laser}} - \tau)} = \frac{fP_{\text{peak}}2r_{\text{laser}}}{P_{\text{peak}} - P_0} \quad (9)$$

FE simulations of the SLS process reported in the literature Dong et al. (2009) usually consider a continuous laser irradiation, even if lasers operate in a PWM regime.

To further investigate this aspect, and determine the range of applicability of the cw assumption, 2D simulations were carried out to calculate thermal cycles $T = f(t)$ induced by either a pulsed laser

Fig. 6. Experimental measurement of the laser/tapped power transmission (a) Experimental set-up (a defocused laser beam is transmitted through a power bed layer, below which a power measurement is carried out), (b) results obtained on PA12 and PEKK powders for a 1.8 W incident power.

mode ($P_{\text{peak}}, \tau_{\text{laser}} f$) or the corresponding cw regime ($P_0 = P_{\text{peak}} \tau f$). The pulsed regime was simulated by considering rectangular laser pulses of τ_{laser} duration. Numerical results (Fig. 10) confirm that for $V < V_{\text{max}}$, the temperature profile, and especially the maximum temperature induced by the real pulsed mode and the equivalent cw regime are nearly the same (maximum variation = ± 10 K), whatever the position considered. Considering laser radii r_{laser} equal to $120 \mu\text{m}$ and frequencies equal to 5 kHz, a fully continuous laser melting was only obtained for $V < 0.5 V_{\text{max}}$ corresponding to an inter-spot distance near r_{laser} (Fig. 9b). Above this value ($= 0.78 \text{ m/s}$), more pronounced thermal variations occur (up to $\Delta T = 50 \text{ K}$), the

surface melting becomes heterogeneous, and a cw irradiation cannot be considered anymore for the simulations. Consequently, experimental conditions have been restricted to scanning speeds below $V = 0.78 \text{ m/s}$.

In Fig. 10, the calculated time maintain above T_0 ($= 520 \text{ K}$) is approximately 0.1 s, which is far from providing a full densification of polymers. Indeed, according to (Frenkel, 1945) the time for densification of polymers t_d can be estimated by Eq. (10) where, η = dynamic viscosity (Pa s), D_{50} = average grain size (m), σ = surface tension ($= 0.003 \text{ N m}^{-1}$ on the two polymers). This makes $t_d = 18 \text{ s}$ on PA12 and $t_d = 25 \text{ s}$ for PEKK, with physical data from Table 1.

Fig. 7. Determination of fusion depths for a single pass melting of (a) PA12 powder bed ($P_0 = 2.5 \text{ W}$, $V = 0.3 \text{ m/s}$, $T_0 = 440 \text{ K}$), (b) PEKK powder bed ($P_0 = 3 \text{ W}$, $V = 0.3 \text{ m/s}$, $T_0 = 600 \text{ K}$).

Fig. 8. Variation of experimental molten depth with the laser process parameter $P_0/V^{0.5}$ (Preheating temperatures T_0 PA12 = 440 K and T_0 PEKK = 600 K).

Fig. 9. (a) Basics of the pulse width modulation (PWM) regime: the laser operates at f frequency and τ pulse duration, (b) Optimization of the scanning speed in PWM regime: for scanning speeds above $0.5V_{\max}$, a discontinuous SLS is obtained.

Such large densification times justify afterwards why SLS machines operate at a temperature level above the crystallization temperature, and maintain this temperature a long time after the laser switch-off.

$$t_d = \frac{\eta D_{50}}{\sigma} \quad (10)$$

3.3.2. Numerical calculation of single fusion lines

In a second step, numerical calculations of fusion depths were carried out for the two polymer powders. As extinction coefficient α (m^{-1}) and spatial distribution $P = f(x, y)$ have been experimentally determined (Section 3.1), the only adjustable factor is the K value Eq. (7), which corrects heat input by considering reflectivity and Mie diffusion losses through the powder bed.

Fig. 10. Thermal simulation of the CO_2 laser heating in PWM mode—Comparison with the equivalent cw heating (PEKK powder, $T_0 = 520$ K, $P_0 = 5$ W, $P_{\text{peak}} = 50$ W, $f = 5$ kHz, $V = 0.5$ m/s).

Fig. 11. Comparison of experimental and simulated molten depths with laser power for a constant scanning speed $V = 0.6$ m/s, and $K = 0.4$: (a) PA12 (simulation with 7500 m^{-1}), (b) PEKK (simulation with $\alpha = 7500 \text{ m}^{-1}$).

The numerical model was shown to reproduce correctly fusion depths on PEKK layers with the use of a $K=0.4$ factor (Fig. 11), which indicate afterwards that approximately 60% of the incident power is lost by reflection or diffusion processes, whereas only 40% contributes to the polymer melting.

However, on PA12 fusion lines, the experimental α value (9000 m^{-1}) was shown to underestimate the real variation of fusion depths. For this reason, alpha was slightly decreased down to 7500 m^{-1} , which is coincidentally the same value than for PEKK, in order to provide a better fitting with experiments. Consequently, similar K and alpha coefficients were numerically identified on PA12 or PEKK polymer layers.

This allowed us estimating numerically the maximum temperatures carried out during the SLS process (Fig. 12). For instance, for a 0.6 m/s scanning speed (Fig. 12), maximum calculated temperatures, averaged on a 0.1 mm diameter around the laser, were comprised between 690 K and 875 K for increasing laser powers.

Even if the cooling part of $T=f(t)$ curves could be correctly reproduced (Fig. 13), the comparison of simulated and experimental $T=f(t)$ thermal profiles was not very successful. Simulations indicate a 740 K maximum temperature, whereas the thermal

measurement indicated maximum temperatures near 635 K. Two explanations are possible: (1) the lack of spatial resolution of the thermal camera sensor ($1 \text{ pixel} = 180 \mu\text{m} \times 180 \mu\text{m}$) which averaged thermal measurements in the laser-powder bed interaction zone, and lowers maximum determined temperatures, (2) a change of emissivity of PEKK above T_m (with a ε decrease), which would minimize the apparent temperature.

On a given powder bed, numerical simulations indicate a quasi-linear variation of surface temperatures with P_0 (Fig. 14). By comparing calculated temperatures, with the surface morphology and the color of the powder bed, temperature thresholds assumed to provoke the thermal degradation (thermo-oxidation) of the polymer were determined. Above 760 K, the first deterioration traces (black spots) are visible on the PEKK surface, and above 825 K, most of the polymer surface is degraded. Such modifications of the polymer surface are mostly due to the limited gas shielding used in the process (the O_2 content was lowered to near 5% due to Argon flow, but was somewhat superior to O_2 levels in industrial machines). However, the model is assumed to allow predicting correctly degradation thresholds.

Fig. 12. Influence of laser power P_0 on the thermal cycles $T=f(t)$ calculated at the surface of the powder bed (PEKK powder, $V = 0.6$ m/s, pre-heating up to 600 K). Maximum temperatures vary between 690 K and 875 K.

Fig. 13. Comparison of experimental and simulated thermal profile (PEKK powder, $V = 0.6$ m/s, $T_0 = 600$ K, $P_0 = 2.6$ W).

Fig. 14. Numerical determination of maximum temperatures, and identification of thermal damage thresholds on PEKK depending on laser power P (W) and scanning speed V (mm/s). Three zones are defined, corresponding to a non-degradation state below 760 K (zone 1) a partial degradation between 760 and 825 K (zone 2) and a full degradation above 825 K (zone 3).

3.3.3. Influence of layer deposition conditions on powder bed temperature

One of the main technical issues of SLS is to maintain stable temperature levels during the SLS process in order to: (1) limit thermally induced deformations and stresses (dependent on thermal gradients G (K/m)) and (2) favor densification Eq. (10). Such deformations are particularly important during crystallization i.e., when the local temperature becomes lower than the crystallization temperature T_c .

Excessive cooling rates are susceptible to occur during layer deposition, because of the lower temperature of the spread powder layer which induces a thermal sinking effect.

A specific numerical approach has been proposed to estimate optimum layer deposition conditions (thickness of deposited powder layer Δh_{powder} , temperature of the deposited powder T_{powder} , deposition speed V_d) allowing maintaining the temperature of powder beds above T_c .

Basically, the numerical model uses a time-dependent Heaviside Step function flc2hs included in COMSOL Multiphysics™ a time variation $\kappa(x, y, z, t)$ of thermal conductivity Eq. (11) to simulate the layer deposition sequence, as already used by Peyre et al. (2008) for the DMD process. This function simulates a continuous transition from a $k=0$ W/mK state (the air) at T_{ext} temperature = (the temperature of the chamber) to a $k(T)$ state (the deposited powder bed). With such an approach, it becomes possible to estimate the local time-temperature cycle $T=f(t)$ of the powder bed surface during layer deposition, and to evaluate the influence of various deposition parameters on fused powder thermal stability.

$$\kappa(T, t, x, z) = k(T)(1 - \text{flc2hs}(x - x_0 - Vt, x_{\text{scale}})) \quad (11)$$

where, flc2hs = Heaviside step function, x_{scale} = transition interval, x_0 = initial positions, V = scanning speed (m/s)

In Fig. 15, the influence of powder layer thickness on surface temperature is reported, considering a powder layer deposited at 373 K on a pre-fused powder bed with a 610 K stabilized temperature following laser surface melting (Fig. 12). A rather low effect is shown on minimal temperatures (5 K), indicating that sinking effects are only a little dependent on powder layers thickness. For

this specific configuration, the minimum temperature reached on the molten layer is 565 K, which level is expected to be below the crystallization start on PEKK.

Considering similar calculations, a processing map for powder deposition conditions (Fig. 15b) was established, allowing the selection of optimum process parameters. This map includes factors such as: the temperature of deposition ($=T_{\text{ext}}$), the temperature of the molten powder bed surface T_{surf} before spreading and the powder layer thickness. As shown in Fig. 15a, this last factor has almost no effect on thermal-microstructural transitions. Similarly, the spreading speed V_{spread} (considered between 0.5 mm/s and 10 mm/s) did not have significant influence on the processing map. Transitions were considered according to the crystallization peak of PEKK (crystallization start at 590 K, crystallization peak at 580 K, crystallization ends at 570 K). Consequently, with the use of such a processing map, one can select optimum powder spreading conditions. For instance, for an external temperature T_{ext} ($\approx$ powder layer temperature) of 480 K, the temperature of the molten powder bed before deposition should be superior to 605 K to fully avoid crystallization. On the other hand, considering a surface temperature before deposition of 590 K, a full crystallization will necessarily occur for $T_{\text{ext}} < 440$ K.

3.4. Selective laser sintering of additive polymer layers

Examples of multi-layers PA12 samples are shown in Fig. 16, for various process conditions applied on five additive layers of simple squared geometries. For low $P/V^{0.5}$ ratios, incomplete melting occurs (right sample from Fig. 16), whereas excessive $P/V^{0.5}$ values provide thermal distortions (left sample on Fig. 16). Finally, optimum process conditions were found (0.2 m/s, 1.6 W) where the density, estimated by a double weighing technique (Dumoulin, 2014), was shown to be approximately 95%, which is rather satisfactory. However, overheating effects at the edge of the samples were evidenced, which have been attributed to a slowing down of the scanning head at the beginning and the end of each fusion lines. This caused a thermally induced curvature of the samples (Fig. 17), despite a pyrometer control of the surface temperature of the

Fig. 15. Numerical calculation of the thermal influence of layer deposition on PEKK. (a) Influence of spread powder layer thickness ($\Delta h = 100 \mu\text{m}$ to $500 \mu\text{m}$, $T_{\text{powder}} = 370 \text{ K}$) on fused powder cooling rates (molten layer temperature = 610 K), (b) numerical processing map considering the temperatures of spread layers (y) and molten layer (x).

Fig. 16. SLS Fabrication of squared PA12 samples obtained with various process conditions ($T_0 = 440 \text{ K}$, five layers).

Fig. 17. Cross section of a squared PA12 sample obtained with five additive layers, ($T_0 = 440 \text{ K}$, $P = 1.6 \text{ W}$, $V = 0.2 \text{ m/s}$). Fused layer thickness h is near $150 \mu\text{m}$, and a $-z$ shift of $-120 \mu\text{m}$ of the building plateau has been used to carry out additive layers.

powder bed, which was stabilized to $T_0 = 440 \text{ K} \pm 5 \text{ K}$ during the whole process.

On PEKK powder beds, thermal distortions were even more pronounced on PEKK samples than on PA12 specimens, for similar $P/V^{0.5}$ ratios (Fig. 18, Fig. 19). Some degradations were also confirmed for similar (P_0 , V) thresholds than those determined

on single fusion lines (Fig. 14). However, optimum porosity rates were shown to be near 15% on PEKK, especially due to a lack of re-melting of interlayer zones. The reason why porosity rate could not be reduced was attributed to the geometrical deformation of the samples during the SLS process that necessitated increasing $-z$ shift values between each layer to avoid contact between the

Fig. 18. SLS Fabrication of squared PEKK samples for different experimental conditions ($T_0 = 600 \text{ K}$, $P = 3.1 \text{ W}$ scan speeds V between 0.1 m/s and 0.8 m/s). A clear polymer degradation is evidenced below 0.3 m/s scan speed.

Fig. 19. Cross section of a squared PEKK sample obtained with five additive layers, ($T_0 = 600$ K, $P = 3$ W, $V = 0.45$ m/s). Fused layer thickness h is near $160\text{ }\mu\text{m}$. For a similar $P/V^{0.5}$ ratio ($3.5\text{ J m}^{-0.5}\text{ s}^{-0.5}$), thermal distortions are more pronounced than for PA12. A $-Z$ -shift of $-180\text{ }\mu\text{m}$ was used to avoid contacts between the spreader and the deformed polymer.

powder scraper and the fused sample. Such extended deformations were due to the combined effect of: (1) the limited work temperature range for PEKK that makes difficult avoiding crystallization, (2) overheating effects near the samples edges due to non-constant scan speeds.

For instance, on the PEKK sample shown in Fig. 19, the measured layer thickness Δh is $160\text{ }\mu\text{m}$, but lower z -shift values could not be used to ensure re-melting of previous layers because of the thermal deformation of the specimen edges that provoked contact with the spread knife. In turn, a $180\text{ }\mu\text{m}$ z -shift was used, which was not sufficient to ensure full re-melting of interlayer zones.

Oncoming developments will focus on the galvanic head system and software with the objective of ensuring more stable scan speeds all along the fusion paths, for limiting overheating effects and associated thermal deformations.

4. Conclusion

The use of combined experimental and numerical developments has been shown to provide useful information concerning laser-matter coupling, molten polymer characteristics and damage thresholds during the SLS process. For the two polymer powders investigated on a specifically designed SLS set-up, transmitted power measurements allowed determining the powder transmission law, which was used as a volume heat source for numerical calculations. Such numerical calculations were shown to reproduce correctly experimental fusion depths with the use of a $K = 0.4$ absorption coefficient, which indicates that most of the incident laser light (60%) is either reflected or diffused in the powder bed. Last, time-temperature profiles were numerically estimated on the PEKK powder, and allowed us determining thermo-oxidative degradation thresholds. In turn, this numerical approach allowed selecting adequate parameters for limiting degradation, and ensuring optimum fusion depths.

In the last stage, the manufacturing of additive layers was shown to be problematic due to non-constant scan speed values along the fusion paths. This provoked local overheating and extensive deformations that impeded a full densification of the SLS parts.

Acknowledgments

Authors would like to thank the whole FADIPLAST consortium for helpful discussions, and the French Ministries of Economy, Industry and employment (Direction of Competitiveness and Services) for financial support. They would like also to thank the following ENSAM students: Boris Valkov, François Sauvage, Cyrielle Louis, Benoit Leleux and Guillaume Gentil, for their active participation in the experimental work.
