Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

ABSTRACT

Crystalline mercury sulfide exists in two drastically different polymorphic forms in different domains of the P,T -diagram: red chain-like insulator α -HgS, stable below 344 °C, and black tetrahedral narrow-band semiconductor β -HgS, stable at higher temperatures. Using pulsed neutron and high-energy X-ray diffraction, we show that these two mercury bonding pattern are present simultaneously in mercury thioarsenate glasses $\text{HgS-As}_2\text{S}_3$. The population and interconnectivity of chain-like and tetrahedral dimorphous forms determine both the structural features and fundamental glass properties (thermal, electronic, etc.). DFT simulations of mercury species and RMC modelling of high-resolution diffraction data provide additional details on local Hg environment and connectivity implying the $(\text{HgS}_{2/2})_m$ oligomeric chains ($1 \leq m \leq 6$) are acting as a network former while the $\text{HgS}_{4/4}$ -related mixed agglomerated units behave as a modifier.

INTRODUCTION

The vast majority of crystals exists in several polymorphic forms in different domains of the P, T -diagram. Liquids and glasses also exhibit density- and entropy-driving polyamorphism,¹⁻⁵ and the question remains whether the liquid-liquid or amorphous-amorphous transformation appears to be a phase transition of the first or second order.⁶⁻⁸ Molecular chalcogenide glasses synthesized in high pressure/high temperature conditions often show two polyamorphic forms simultaneously, i.e., a molecular cage and a network-related motif.^{9,10} The network-related population increases with applied pressure squashing the cage molecules. Here we report a different phenomenon: mercury sulfide dimorphism in network glasses synthesized in usual conditions without external stimuli. The term 'dimorphism' in this particular glass system is used to emphasize the origin of $\text{HgS}_{2/2}$ and $\text{HgS}_{4/4}$ units deriving from the two drastically different polymorphic forms of mercury sulfide, low-temperature cinnabar $\alpha\text{-HgS}$ and high-temperature metacinnabar $\beta\text{-HgS}$.

Chalcogenide glasses transparent in the far IR region ($\lambda > 15 \text{ mm}$) are critically important for many optical systems. Selective remote IR spectroscopy of various biotoxin and gas species, thermal imaging, interstellar IR detection of life signature at exoplanetary systems, etc.¹¹⁻¹⁴ represent only a few examples. Mercury chalcogenide glasses are particularly promising for these applications. Surprisingly, very little is known about their structure and properties. Using Raman spectroscopy and DFT modelling, we have shown recently that mercury thioarsenate glasses $\text{HgS-As}_2\text{S}_3$ form a hybrid Hg-S chain/ As-S pyramidal network.¹⁵ Nevertheless, the presence of a small fraction of $\text{HgS}_{4/4}$ tetrahedral units in the hybrid network cannot be excluded completely since the Raman spectra of crystalline references, trigonal cinnabar $\alpha\text{-HgS}$ (Hg-S

chains) and cubic metacinnabar β -HgS ($\text{HgS}_{4/4}$ tetrahedra), were found to be rather similar in the stretching region.¹⁶⁻¹⁸ Consequently, the two possible structural motifs in glasses may have similar Hg-S stretching frequencies. Pulsed neutron and high-energy X-ray diffraction over a wide Q -range combined with DFT simulation of 4-fold coordinated mercury entities and RMC modelling of the diffraction data are necessary to solve this structural puzzle. High-resolution diffraction results and comprehensive analysis allow a reliable conclusion to be drawn concerning dual structural role of mercury acting as either a network-former or a modifier. We will show that this structural analysis appears to be consistent with basic thermal and electronic glass properties. In addition, it should also be noted the lack of diffraction studies for mercury chalcogenide glasses probably related to high mercury absorption for both X-rays ($Z_{\text{Hg}} = 80$) and neutrons ($\sigma_{\text{abs}} = 372.3$ barns¹⁹). The paper will unveil the structural features of these exciting glasses in the Q - and r -space. This understanding will be beneficial for their practical applications in optical systems and chemical sensing.

EXPERIMENTAL SECTION

Glass preparation. The quasi-binary $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ samples ($x = 0.0, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5$) were prepared from HgS and As_2S_3 . Red mercury sulfide α -HgS (99.99% pure, Sigma-Aldrich) was used for synthesis of HgS– As_2S_3 samples without additional purification. Arsenic sulfide As_2S_3 was prepared from arsenic pieces (99.9999% pure, Cerac) and sulfur pellets (99.999% pure, Acros Organics). Arsenic and sulfur were purified from As_2O_3 and SO_2 oxides at the surface by heating under vacuum at 320 °C and 130 °C, respectively. The detailed synthesis and homogenization procedure was described elsewhere.¹⁵ The obtained glasses were

found to be homogeneous on macroscopic (1-100 μm) and mesoscopic (10-1000 $\text{\AA}$) scale (a single glass transition over the entire glass forming range, $0.0 \leq x \leq 0.5$,¹⁵ and the absence of small-angle neutron and X-ray scattering in contrast to a typical behavior of phase-separated glasses; Fig. S1, Supporting information).

Diffraction measurements. Neutron diffraction experiments were carried out using the ISIS spallation neutron source (Rutherford-Appleton Laboratory, UK) and the SNS facility (Oak-Ridge National Laboratory, USA). The SANDALS ($x = 0, 0.1, 0.2$, and 0.4 samples), GEM ($x = 0.05$) and NOMAD ($x = 0.05, 0.3, 0.5$) diffractometers²⁰⁻²³ at ISIS and SNS provide diffraction data over an extended range in reciprocal space (values of scattering vector $Q = 4\pi \sin\theta/\lambda$ up to $50 \text{ \AA}^{-1}$; where 2θ is the scattering angle, λ the neutron wavelength), leading to high resolution in real space. The neutron diffraction data were corrected^{22,24} for background and container scattering, self-attenuation, multiple scattering, and inelasticity (Placzek) effects to obtain the total neutron structure factor $S_N(Q)$.

High-energy X-ray diffraction experiments were conducted at the 6-ID-D beam line²⁵ at APS (Argonne National Laboratory, USA). The X-ray energy was 100 keV, providing data at Q values up to $30 \text{ \AA}^{-1}$. A 2D setup was used for data collection with a Perkin Elmer model 1621 X-ray area detector. The two dimensional diffraction patterns were reduced using the Fit2D²⁶ software. The measured background intensity was subtracted and corrections were made for the different detector geometries and efficiencies, sample self-attenuation and Compton scattering using standard procedures^{27,28} giving the total X-ray structure factor $S_X(Q)$.

DFT simulation. The DFT calculations have been carried out using GAUSSIAN 09 software²⁹ associated with its graphical user interface GaussView. In order to find a compromise

between the cost of the calculations and the accuracy of the results, structural optimization and harmonic vibrational frequency calculations were performed for size-limited clusters composed of isolated $\text{HgS}_4(\text{H}_4)$ and $\text{HgS}_3(\text{H}_3)$ units, mixed $\text{Hg}_2\text{S}_5(\text{H}_4)$, $\text{Hg}_3\text{S}_6(\text{H}_4)$, $\text{Hg}_3\text{S}_8(\text{H}_6)$ and hybrid $\text{HgAsS}_6(\text{H}_5)$ clusters. Our previous DFT modelling of the chalcogenide glass vibrational properties^{15,30} has shown that the above cluster size is sufficient to adequately represent the characteristic vibration modes in the glass and follow compositional trends. The terminal hydrogen atoms will be omitted in further discussions.

The DFT calculations were carried out with the Becke³¹ three parameters hybrid exchange functional and the Lee–Yang–Parr correlation functional (B3LYP).³² The rather large 6-311G++(3df,2p) basis-set was used for arsenic, sulfur and hydrogen. In the case of atoms with a heavy nucleus like mercury, relativistic effects due to the inner core electrons having a velocity close to the speed of light should be taken into account. For Hg atoms, we have declared in the input file an external pseudo-potential or Effective Core Potential available in the Environment Molecular Science Library.³³ The small-core relativistic pseudo-potential basis set (cc-pVTZ-PP)³⁴ was specifically employed. All the structures were optimized using the tight convergence option ensuring adequate convergence and reliability of computed wavenumbers.

Reverse Monte Carlo modelling. The diffraction data of the $x = 0.4$ glass were used for Reverse Monte Carlo (RMC) modelling. Initial random configurations of 760 and 7600 atoms were created and refined using the RMC_POT++ package^{35,36} which is a C++ implementation of the RMC algorithm³⁷⁻⁴⁰ for deriving structures of disordered materials from experimental data. The small configuration was used to adjust constraints; the larger model (800 Hg, 2400 As and 4400 S atoms positioned inside a cubic box with a side length of 58.26 Å matching the experimental number density) was applied for final simulation. Atomic configurations were

generated first by running a conventional hard sphere Monte Carlo simulation. The following *a priori* information was used to constrain the configurations: (i) the hard-sphere closest approaches between different types of atoms (cut-off distances), and (ii) the coordination number constraints. The cut-off distances are given in Table 1. The measured neutron and X-ray structure factors, $S_N(Q)$ and $S_X(Q)$, and neutron pair distribution function $g_N(r)$ were then used to generate RMC models. The simulated structural functions, calculated from a configuration of atomic positions with periodic boundary conditions, were refined in comparison with experimental data. A typical number of generated/accepted moves for the larger simulation box was about $2.0 \times 10^7/1.6 \times 10^6$ in order to minimize the differences between a simulated and experimental function. RMC simulations were performed using a multiprocessor calculation server; the algorithm converges to a local minimum during a few hours or a few days depending on number of atoms in the configuration.

Table 1. Hard-sphere closest approaches (cut-off distances) for different atom pairs used in RMC modelling of 0.4HgS-0.6As₂S₃ glass

Atom pair	As–S	Hg–S	As–As	As–Hg	Hg–Hg	S–S
Cut-off distance (Å)	2.0	2.15	2.8	3.3	3.3	2.8

RESULTS AND DISCUSSION

Diffraction: *Q*-space. Weighted average structure factors $S(Q)$ were derived from the measured scattering cross section per atom $d\sigma/d\Omega$ through the relation

$$\frac{d\sigma}{d\Omega} = \left| \sum_a c_a \bar{b}_a \right|^2 (S(Q) - 1) + \sum_a c_a \bar{b}_a^2, \tag{1}$$

in the case of neutron scattering, where c_a , $\bar{b}_a$ and $\bar{b}_a^2$ are, respectively, the atomic concentration, the average (over isotopes and spin states) of the neutron–nucleus scattering length, and the mean square scattering length of element a . In the X-ray case, $\bar{b}_a$ in eq. (1) is replaced by $f_a(Q)$, the atomic scattering factor of element a , which is Q dependent.

Figure 1. Typical (a) neutron $S_N(Q)$ and (b) X-ray $S_X(Q)$ structure factors of mercury thioarsenate glasses $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$, $0 \leq x \leq 0.5$, shown over a limited Q -range. Remarkable changes in the low- Q region below $2 \text{ \AA}^{-1}$ are highlighted in grey. RMC simulated $S_N(Q)$ and $S_X(Q)$ for the $x = 0.4$ glass are shown by the dashed lines.

Typical neutron and X-ray structure factors of mercury thioarsenate glasses $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ are shown in Fig. 1. We note distinct high- Q oscillations, observed up to $40 \text{ \AA}^{-1}$ for glassy As_2S_3 , which are decreasing in amplitude with increasing HgS content x . Small Bragg peaks, related to cubic metacinnabar β -HgS, were observed only for large $x = 0.5$ neutron sample ($\approx 3 \text{ g}$) and absent for all other glasses including tiny $x = 0.5$ X-ray specimen, synthesized and quenched in thin-walled silica tube in small quantity (0.1 g). The most prominent changes were

observed in the low- Q region, $Q < 2 \text{ \AA}^{-1}$, highlighted in grey in Fig. 1. The published data⁴¹⁻⁴⁵ for vitreous $g\text{-As}_2\text{S}_3$ are similar to our results.

Glassy arsenic sulfide is characterized by a well-defined intermediate-range order (IRO) manifested by the first sharp diffraction peak (FSDP) at $Q_0 = 1.24 \text{ \AA}^{-1}$.⁴¹⁻⁴⁷ As-As correlations with a characteristic length scale $L_0 \cong 2\pi/Q_0 = 5.1 \text{ \AA}$ are responsible for the FSDP^{43,48-50} and represent average repeating As-As distances within or between As_nS_n rings, the origin of intermediate-range ordering in $g\text{-As}_2\text{S}_3$. Layered monoclinic orpiment $c\text{-As}_2\text{S}_3$ consists of As_6S_6 rings and each arsenic atom participates in three neighboring rings.⁵¹ The As-As intra-ring and short interlayer correlations in $c\text{-As}_2\text{S}_3$ cover the $5.05 \leq r(\text{As-As}) \leq 5.85 \text{ \AA}$ range. The ring size n appears to be variable in glassy arsenic sulfide.⁵²

A new low- Q feature appears and grows with increasing mercury sulfide content in $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ glasses. In order to extract the parameters of the two pre-peaks, a Voigt function was used to approximate the background underneath the features,²⁴ allowing the pre-peaks to be isolated and fitted with Gaussians. Figure 2 shows the two pre-peaks as a function of x .

Figure 2. Two pre-peaks at $Q_{0A} \approx 1.3 \text{ \AA}^{-1}$ (As-As correlations) and $Q_{0B} \approx 1.7 \text{ \AA}^{-1}$ (Hg-Hg correlations) isolated from (a) neutron $S_N(Q)$ and (b) X-ray $S_X(Q)$ structure factors for $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ glasses.

The first pre-peak at $Q_{0A} \approx 1.3 \text{ \AA}^{-1}$, corresponding to As-As IRO correlations in the As_2S_3 host matrix, decreases with increasing x . Its amplitude A_{0A} in neutron data is slightly higher than that for hard X-rays, consistent with neutron and X-ray As-As weighting factors in the mercury thioarsenate glasses, $1.10 \leq \frac{W_{\text{As-As}}^N}{W_{\text{As-As}}^X} \leq 1.26$, where $w_{ab}^N = (2 - \delta_{ab}) \frac{c_a \bar{b}_a c_b \bar{b}_b}{|\sum_a c_a \bar{b}_a|^2}$ is the neutron weighting factor for the atom pair (a,b) and δ_{ab} is the Kronecker delta function. In the X-ray case, $\bar{b}_a$ is replaced by Q -dependent atomic scattering factor $f_a(Q)$, see also eq. (1) for further details. In contrast, the second pre-peak at $Q_{0B} \approx 1.7 \text{ \AA}^{-1}$ grows with mercury sulfide content, and the A_{0B} amplitude is slightly higher for the $S_X(Q)$ structure factors, correlating with Hg-Hg weighting factors, $0.70 \leq \frac{W_{\text{Hg-Hg}}^N}{W_{\text{Hg-Hg}}^X} \leq 0.80$. Spatial periodicity related to the second pre-peak, i.e., a characteristic length scale L_{0B} deduced from Q_{0B} , $L_{0B} \cong 2\pi/Q_{0B} = 3.7 \text{ \AA}$, is similar to Hg-Hg intrachain second neighbor distance in α -HgS ($3.75 \text{ \AA}$)⁵³ and distinctly shorter than the closest Hg-Hg interchain correlations (4.10 - $4.15 \text{ \AA}$)⁵³ or Hg-Hg second neighbor contacts in β -HgS ($4.14 \text{ \AA}$).⁵⁴ Consequently, the appearance and position of the second pre-peak seems to be related to Hg-Hg correlations in $(\text{HgS}_{2/2})_m$ zig-zag chains existing in hybrid chain/pyramidal network of HgS- As_2S_3 glasses.

The origin of the two pre-peaks is clearly seen on difference structure factors $\Delta S(Q)$ without As-As or Hg-Hg correlations (Fig. 3) calculated using a combination of neutron and high-energy X-ray diffraction data and removing Hg-Hg correlations as an example:

$$\Delta S_{\text{-HgHg}}(Q) - 1 = \left\{ [S_X(Q) - 1] - \frac{W_{\text{HgHg}}^X(Q)}{W_{\text{HgHg}}^N} [S_N(Q) - 1] \right\} \frac{W_{\text{AsAs}}^X(Q)}{W_{\text{AsAs}}^X(Q) - \frac{W_{\text{HgHg}}^X(Q)}{W_{\text{HgHg}}^N} W_{\text{AsAs}}^N}, \quad (2)$$

where $S_X(Q)$ and $S_N(Q)$ are the Faber-Ziman X-ray and neutron structure factors, $W_{ab}^X(Q)$ are the Q -dependent X-ray weighting factors, and W_{ab}^N are the neutron weighting coefficients. The second term in eq. (2) normalizes the difference $\Delta S(Q)$ structure factor to the original (before subtraction) As-As correlations.

Figure 3. The 1.3 Å⁻¹ (As-As) and 1.7 Å⁻¹ (Hg-Hg) pre-peaks isolated from the difference structure factors $\Delta S(Q)$ without As-As (the dashed line) or Hg-Hg correlations (the solid line) for the $x = 0.4$ glass.

The pre-peak at 1.7 Å⁻¹ is absent for $\Delta S(Q)$ without Hg-Hg correlations, while the subtraction procedure for the 1.3 Å⁻¹ pre-peak leaves some residuals on $\Delta S(Q)$ without As-As correlations, Fig. 3. Nevertheless, the negative or positive amplitude of these residuals is small compared to that of the 1.3 Å⁻¹ pre-peak. We have also verified a possible implication of As-Hg correlations in the 1.7 Å⁻¹ pre-peak. Subtracting the As-Hg term yields strong negative amplitude at ≈ 1.7 Å⁻¹ and also affects the As-As pre-peak at ≈ 1.3 Å⁻¹, Fig. S2 (Supporting information), since the As-Hg weighting is larger than the Hg-Hg weighting for all compositions studied, for both X-rays and neutrons. Consequently, we are ruling out this possibility.

Figure 4. The $1.3 \text{ \AA}^{-1}$ (As-As) and $1.7 \text{ \AA}^{-1}$ (Hg-Hg) pre-peak (a) position and (b) amplitude in mercury thioarsenate glasses. Circles and squares correspond to neutron and X-ray data, respectively. The threshold concentration $x_0 \approx 0.3$ between Regions 1 and 2 is highlighted in blue. The lines are drawn as a guide to the eye.

The composition dependences of the pre-peak amplitudes (A_{0A}, A_{0B}) and positions (Q_{0A}, Q_{0B}), shown in Fig. 4, exhibit a critical behavior with the threshold concentration $x_0 \approx 0.3$. A nearly linear decrease of the $A_{0A}(x)$ amplitude below x_0 (Region 1) is simply related to a diminishing As_2S_3 fraction, $1-x$, with the increasing mercury sulfide content x ; $A_{0A}(x)$ tends to 0 as $x \rightarrow 1$. The $A_{0B}(x)$ amplitude increases monotonically with x up to $x_0 \approx 0.3$. The both trends change for HgS-rich glasses. The $1.3 \text{ \AA}^{-1}$ pre-peak starts to disappear rapidly at $x \geq x_0$ (Region 2), and $A_{0A}(x)$ is expected to be zero just above the glass-forming limit. Simultaneously, one observes a distinct increase of $Q_{0A}(x)$, which is constant below x_0 . On the

other hand, the $1.7 \text{ \AA}^{-1}$ pre-peak stops growing above x_0 indicating a limiting role of $(\text{HgS}_{2/2})_m$ helical chains in further network transformation.

Diffraction: r -space. Total correlation functions $T_N(r)$ and $T_X(r)$ were derived through the usual Fourier transform,

$$T(r) = 4\pi\rho_0 r + \frac{2}{\pi} \int_0^{Q_{\max}} Q[S(Q) - 1] \sin Qr M(Q) dQ, \quad (3)$$

where ρ_0 is the total number density, and $M(Q)$ is the Lorch modification function.⁵⁵ Results for the $\text{HgS-As}_2\text{S}_3$ glasses are shown in Fig. 5 taking $Q_{\max} = 30 \text{ \AA}^{-1}$ for both neutron and X-ray data for comparative purposes. The atomic number densities were derived from the experimental glass density values.¹⁵

The total correlation function defined in eq. (3) is a weighted average of partial total correlation functions for the different atom pairs (a, b) :

$$T(r) = \sum_{ab} W_{ab} T_{ab}(r) = \sum_{ab} c_a c_b \frac{\bar{b}_a \bar{b}_b}{|\sum_a c_a \bar{b}_a|^2} T_{ab}(r). \quad (4)$$

A weighted average coordination number for a peak in $T(r)$ extending from r_x to r_y is defined as

$$C = \int_{r_x}^{r_y} r T(r) dr. \quad (5)$$

Analogously to eq. (4), this C is related to the partial coordination numbers N_{ab} expressing the average number of b -atoms within the $r_y - r_x$ range from an a -atom at the origin⁵⁶

$$C = \sum_{ab} w_{ab} N_{ab} = \sum_{ab} c_a \frac{\bar{b}_a \bar{b}_b}{|\sum_a c_a \bar{b}_a|^2} N_{ab}. \quad (6)$$

Figure 5. (a) Neutron $T_N(r)$ and (b) X-ray $T_X(r)$ total correlation functions of $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ glasses. The first neighbor peak at ≈ 2.3 Å, the second neighbor peak at ≈ 3.5 Å, and the As_nS_n center-center correlations at ≈ 5.2 Å are highlighted in yellow, green and orange respectively.

Glassy As_2S_3 shows three characteristic peaks in real-space functions: (i) a narrow peak at 2.27 Å corresponding to As-S first neighbor correlations; (ii) a broad peak at ≈ 3.5 Å related to As-As, S-S and As-S second neighbor intra-layer contacts and shortest interlayer correlations; (iii) a distinct feature at ≈ 5.2 Å reflecting center-center correlations between As_nS_n rings (As_6S_6 in monoclinic $c\text{-As}_2\text{S}_3$). The area of the 2.27 Å peak confirms trigonal arsenic coordination, $N_{\text{As-S}} \approx 3$.

The 2.27 Å peak decreases in $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$ glasses following the $(1-x)$ concentration factor. In addition, a distinct asymmetric high- r broadening is observed with increasing x . This broadening is expected since the Hg-S first neighbour distance in trigonal cinnabar $\alpha\text{-HgS}$ is 2.38 Å and that in cubic metacinnabar $\beta\text{-HgS}$ is 2.54 Å.^{53,54} A new broad feature at ≈ 4 Å appears

and increases with x . This change is also expected since the second neighbour correlations at $4 \text{ \AA} \leq r \leq 5 \text{ \AA}$ exist in both α - and β -HgS. Finally, the $5.2 \text{ \AA}$ feature broadens and becomes less intense with increasing x .

Figure 6. Difference total correlation functions $\Delta T(r)$ for HgS-As₂S₃ glasses obtained by combination of neutron and X-ray diffraction data for each glass composition. The solid lines correspond to $\Delta T(r)$ without As-S correlations. The dotted lines are $\Delta T(r)$'s without Hg-S correlations. The As-S and Hg-S first neighbor correlations are highlighted in yellow and dark yellow, respectively.

Two contributions to the first neighbor peak at $\approx 2.3 \text{ \AA}$ are clearly visible on difference correlation functions $\Delta T(r)$, Fig. 6, obtained using a combination of neutron and X-ray diffraction data for each glass composition, eq. (2). Different neutron and X-ray weighting factors for As-S, $W_{\text{As-S}}^N(x)$ and $W_{\text{As-S}}^X(x)$, and Hg-S pairs, $W_{\text{Hg-S}}^N(x)$ and $W_{\text{Hg-S}}^X(x)$, allow $\Delta T(r)$ to be calculated without As-S (the solid lines in Fig. 6) or Hg-S correlations (the dotted

lines in Fig. 6). As a result, the overlapping first neighbor peak at ≈ 2.3 Å for $T_N(r)$'s and $T_X(r)$'s (Fig. 5) appears to be split into two features in $\Delta T(r)$ functions.

Figure 7. A three-peak fitting of the first feature in (a) neutron $T_N(r)$ and (b) X-ray $T_X(r)$ total correlation functions for the $x = 0.4$ glass. The As–S, two-fold $\text{Hg}_{2\text{F}}\text{–S}$ and four-fold $\text{Hg}_{4\text{F}}\text{–S}$ correlations are highlighted in red, green and blue, respectively.

Fitting the first peak in $T_N(r)$ and $T_X(r)$ with two Gaussians yields $N_{\text{As–S}} \approx 3$ and $N_{\text{Hg–S}} \geq 2$, the Hg–S coordination number is increasing with x . In other words, the four-fold coordinated mercury species appear in the glass network. In contrast, the trigonal arsenic coordination remains intact, consistent with Raman spectroscopy data.¹⁵ The fit quality deteriorates with x since $r(\text{Hg}_{4\text{F}}\text{–S}) > r(\text{Hg}_{2\text{F}}\text{–S})$, 2.54 vs. 2.38 Å in crystalline β - and α -HgS, respectively. Consequently, a three-peak fitting (Fig. 7) was necessary with the following constraint on $C_{\text{Hg}}^{2\text{F}}$ and $C_{\text{Hg}}^{4\text{F}}$ peak areas:

$$2 - \frac{C_{\text{Hg}}^{2\text{F}}}{w_{\text{Hg–S}}} = \frac{1}{2} \frac{C_{\text{Hg}}^{4\text{F}}}{w_{\text{Hg–S}}}, \quad (7)$$

where $C_{\text{Hg}}^{2\text{F}}$ and $C_{\text{Hg}}^{4\text{F}}$ are the peak areas, defined by eq. (5), corresponding to 2-fold and 4-fold coordinated mercury, $w_{\text{Hg–S}}$ is the neutron or X-ray Hg–S weighting factor. The obtained partial

coordination numbers N_{Hg}^{2F} and N_{Hg}^{4F} were used to calculate the fraction of 4-fold coordinated Hg species f_{Hg}^{4F} :

$$f_{\text{Hg}}^{4F} = \frac{N_{\text{Hg-S}}^{4F}}{4} = 1 - \frac{N_{\text{Hg-S}}^{2F}}{2}. \quad (8)$$

Figure 8. (a) The fraction of four-fold coordinated mercury f_{Hg}^{4F} and (b) the first neighbor As-S, Hg_{2F} -S and Hg_{4F} -S distances in $\text{HgS-As}_2\text{S}_3$ glasses plotted as a function of x . The average (neutron and X-ray) values are drawn for f_{Hg}^{4F} . The $x = 0.5$ composition is characterized by large n/X difference, probably because the neutron sample is partly crystallized. The first neighbor distances are shown separately for neutrons (circles) and X-rays (squares). The threshold concentration $x_0 \approx 0.3$ is highlighted in blue. The lines are drawn as a guide to the eye.

The f_{Hg}^{4F} fraction is negligible at $x \leq 0.1$ but increases with mercury sulfide content reaching $f_{\text{Hg}}^{4F} \approx 0.3$ for equimolar $\text{HgS/As}_2\text{S}_3$ composition ($x = 0.5$), Fig. 8. The fitting results are given in Table 2.

Table 2. Structural parameters of HgS-As₂S₃ glasses obtained using pulsed neutron and high-energy X-ray diffraction: first neighbor interatomic distances, $r(\text{As-S})$, $r(\text{Hg}_{2F}\text{-S})$ and $r(\text{Hg}_{4F}\text{-S})$, for arsenic, two-fold and 4-fold coordinated mercury species; partial coordination numbers, $N_{\text{As-S}}$, $N_{\text{Hg-S}}^{2F}$, and $N_{\text{Hg-S}}^{4F}$.

The derived fraction $f_{\text{Hg}}^{4F} \leq 0.3$ indicates that a majority of mercury species is two-fold coordinated and the hybrid chain/pyramidal network is the main structural motif in mercury thioarsenate glasses. A higher flexibility of the hybrid network compared to $g\text{-As}_2\text{S}_3$ results in lower glass transition temperatures $T_g(x)$, observed experimentally.¹⁵

The critical behavior is less evident for structural parameters in the r -space. We should note a certain discontinuity for f_{Hg}^{4F} at x_0 . The two Hg-S distances also start decreasing above x_0 (Region 2), $2.36 \text{ \AA} \leq r(\text{Hg}_{2F}-\text{S}) \leq 2.39 \text{ \AA}$, and $2.41 \text{ \AA} \leq r(\text{Hg}_{4F}-\text{S}) \leq 2.49 \text{ \AA}$. The latter distance appears to be distinctly shorter than $r(\text{Hg}_{4F}-\text{S}) = 2.54 \text{ \AA}$ in cubic metacinnabar β -HgS. However, the As-S first neighbor separation remains invariant over the entire composition range, $r(\text{As}-\text{S}) \approx 2.27 \text{ \AA}$.

Raman signature of 4-fold coordinated mercury species calculated using DFT. DFT modelling of Raman spectra for four-fold coordinated mercury species has shown several interesting features: (1) a contrasting stability of isolated HgS_4 molecules, (2) similar Hg-S symmetric stretching frequencies for two-fold and 4-fold coordinated Hg entities with a distinct red shift for HgS_4 units, and (3) a remarkable blue shift of $\approx 35 \text{ cm}^{-1}$ between A_1 symmetric stretching modes in crystalline HgS polymorphs and small Hg-S clusters in contrast to a resemblance of DFT simulated and experimental frequencies in glasses.

First, an isolated HgS_4 tetrahedral molecule (T_d symmetry) appears to be unstable and transforms into an HgS_4 square (D_{4h} symmetry), Fig. 9(a). The calculated Hg-S interatomic distances, $2.42 \text{ \AA}$, are shorter than those in cubic metacinnabar β -HgS but similar to the $\text{Hg}_{4F}-\text{S}$ first neighbour contacts observed in diffraction experiments of $\text{HgS-As}_2\text{S}_3$ glasses, Fig. 8(b). A DFT Raman spectrum of the HgS_4 square in the stretching region exhibits a bimodal feature: Hg-S asymmetric and symmetric stretch at 269 and 287 cm^{-1} , respectively, Fig. 9(b). Fixed tetrahedral geometry of HgS_4 with identical $\angle\text{S-Hg-S}$ angles of 109.47° yields rather similar Raman spectrum. Nevertheless, negative (imaginary) frequencies for some bending and H-related modes, are indicating again that isolated tetrahedral mercury species remain unstable.

Figure 9. (a) Schematic representation of small Hg-S and Hg-As-S clusters used for DFT modelling; the terminal hydrogen species are omitted; (b) DFT Raman spectra in the stretching domain for (1) HgS₄ square, (3) HgAsS₆ hybrid cluster, (4) Hg₂S₅ mixed unit, and (5) Hg₂S₃ oligomer,¹⁵ plotted using fixed FWHM of 8 cm⁻¹. The hydrogen-related modes are removed from the spectra. The spectrum for (2) isolated HgS₄ tetrahedron is not shown because of imaginary frequencies. The highlighted features in yellow at 265-305 cm⁻¹ correspond to symmetric Hg-S stretching in mercury sulfide related fragments. The As-S stretching modes in hybrid HgAsS₆ are highlighted in green. The dash-dotted and dashed lines at 247 and 256 cm⁻¹ show the positions of the most intense vibrational modes in cubic metacinnabar β-HgS and trigonal cinnabar α-HgS, respectively.¹⁶⁻¹⁸ A typical difference Raman spectrum for (6) the *x* = 0.5 glass is also shown.¹⁵

The tetrahedral instability persists in Hg₂S₅, Hg₃S₆, Hg₃S₈ mixed units, and hybrid HgAsS₆ clusters yielding the approximate D_{4h} symmetry, Fig. 9(a), starting from regular T_d configuration for an HgS₄ molecule, Fig. S3 (Supporting information). The optimized geometry of HgS₄ square is similar in all cases: the average Hg-S distances remain 2.43±0.02 Å, while the ∠S-Hg-S bond angles are 90±3° and 178±2° for sulfur atoms in *cis*- or *trans*-position,

respectively. We note, however, the increasing distortion of square geometry for mixed and hybrid clusters compared to a single HgS_4 molecule, evidenced by variability of bond lengths and angles, i.e., $90.0\pm0.2^\circ$ (HgS_4) vs. $90\pm3^\circ$ (Hg_2S_5 or HgAsS_6).

The $-\text{S}-\text{Hg}-\text{S}-$ chain fragments are characterized by shorter bonds, $2.36\pm0.01\text{ \AA}$, and usual bond angles for chains, $\angle\text{S}-\text{Hg}-\text{S} = 176\pm3^\circ$. These results are consistent with those reported previously¹⁵ and diffraction data, Fig. 8(b). The AsS_3 pyramidal units show a distorted C_{3v} symmetry with similar As-S distances, $2.28\text{ \AA}$, but different angular parameters, $\angle\text{S}-\text{As}-\text{S} = 97\pm7^\circ$. The full set of optimized geometry for DFT-relaxed clusters is given in Table 3.

Table 3. Optimized geometry parameters (mercury-sulfur, $r(\text{Hg}_{2F}-\text{S})/r(\text{Hg}_{4F}-\text{S})$, and arsenic-sulfur, $r(\text{As}-\text{S})$, interatomic distances, and related bond angles) of isolated HgS_4 ,[§] mixed Hg_2S_5 ,[§] Hg_3S_6 ,[§] Hg_3S_8 ,[§] and hybrid HgAsS_6 ,[§] clusters used in DFT modelling of vibrational properties.

[§] S atoms in *trans*-position

The last digit(s) in parentheses corresponds to the mean-square deviation (MSD) of the average calculated values. The missing MSD for the calculated geometry parameters means either a single calculated value or a negligible difference between several nearly identical geometry parameters.

The tetrahedral instability of HgS_4 molecules in DFT simulations is related to the “standard” $T = 0$ K ground state of analyzed systems. As a result, it is consistent with thermodynamic stability range of high-temperature cubic β - HgS , metastable below 344°C , in contrast to low-temperature trigonal cinnabar. A non-negligible distortion of HgS_4 square geometry in mixed and hybrid clusters, Table 3, suggests a variety of 4-fold coordinated mercury local environments in the $\text{HgS-As}_2\text{S}_3$ glasses.

The calculated frequencies of the most intense Hg-S symmetric stretching modes in DFT Raman spectra of different 4-fold coordinated mercury species are red-shifted compared to analogous A_1 modes in $(\text{HgS}_{2/2})_m$ chains and hybrid units, see Fig. 9, Fig. S4 (Supporting information) and Ref. [15]. For example, a red shift of -24 cm^{-1} is observed between the Hg_2S_3 oligomer and Hg_2S_5 mixed unit. This finding correlates with experimental Raman results¹⁶⁻¹⁸ and a small but distinct red shift (-9 cm^{-1}) between α - and β - HgS , schematically shown in Fig. 9(b) by the dashed and dash-dotted lines, respectively. On the other hand, the observed blue shift $\Delta\omega = \omega_{\text{DFT}} - \omega_{\text{cr}}$ between the simulated DFT frequencies and crystal data, $+20\text{ cm}^{-1} \leq \Delta\omega \leq +50\text{ cm}^{-1}$, is certainly related to enhanced intrachain/intra-fragment interactions in small clusters compared to bulk 1D (α - HgS) or 3D (β - HgS) network, discussed in details previously.¹⁵ However, the calculated frequencies are in good agreement with experimental glass results, Fig. 9(b), extending the hypothesis of strong intra-fragment interactions to Hg-related structural motifs in glasses.

The presence of $\text{HgS}_{4/4}$ units in mercury thioarsenate glasses, evidenced by neutron and high-energy X-ray diffraction, is consistent with Raman data and DFT simulations. The Hg-S symmetric stretching modes of both two-fold and 4-fold coordinated mercury entities in glasses

are overlapping and hardly distinguishable. Nevertheless, a small red shift in A_1 stretching frequencies between the two species implies an increasing linewidth and peak position evolution with increasing HgS content. The two trends (a 40% increase in FWHM and a systematic red shift of -11 cm^{-1}) are observed experimentally.¹⁵

Using DFT, we have also verified a possible implication of 3-fold coordinated mercury in the structural organization of the HgS-As₂S₃ glasses. The DFT modelling of a trigonal Hg-S cluster has shown its instability. Starting from the initial HgS₃ pyramidal configuration with identical Hg-S distances of 2.40 Å and S-Hg-S angles (109°), one of the three sulfur species is rapidly moving out from the central mercury atom, 3 Å after 16 DFT steps (Fig. S5, Supporting information). The remaining HgS₂ unit transforms into a typical HgS_{2/2} chain fragment,¹⁵ $r(\text{Hg}_{2F} - \text{S}) = 2.37\text{ Å}$, $\angle\text{S-Hg-S} \approx 180^\circ$.

Characteristic features in RMC generated glass structure model. As expected, a good agreement has been found between the experimental and simulated neutron and X-ray total structure factors $S_N(Q)$ and $S_X(Q)$, Fig. 1, and the neutron pair distribution function $g_N(r)$ for the $x = 0.4$ glass, Fig. S6 (Supporting information). A snapshot of the 58.26 Å RMC simulation box with 7600 atoms (Hg, As, S) corresponding to the $x = 0.4$ glass chemical composition is shown in Fig. 10(a). Typical RMC generated configurations for (HgS_{2/2})_m chain fragments, isolated and agglomerated HgS_{4/4} structural units are visualized in Fig. 10(b). The partial pair distribution functions $g_{ij}(r)$ are given in Fig. 11 and the bond angle distributions ($\angle\text{S-As-S}$, $\angle\text{As-S-As}$, $\angle\text{S-Hg-S}$, and $\angle\text{Hg-S-Hg}$) in Fig. 12.

The RMC generated 3D structural model for the $x = 0.4$ glass reproduces well the results of direct $T_N(r)$ and $T_X(r)$ fitting. The majority of arsenic species (94.8 %) are three-fold

coordinated. The fraction of 4-fold coordinated mercury is $f_{\text{Hg}}^{4F} = 0.16$ vs. 0.18 ± 0.02 for direct fitting, Fig. 8(a). The distribution of arsenic and mercury coordination numbers is given in Fig. S7 (Supporting information). It should be noted that in the RMC modelling we have assumed a bimodal distribution of mercury coordination centered at $N_{\text{Hg-S}} = 2$ and $N_{\text{Hg-S}} = 4$ and used the respective coordination constraints. A significant implication of 3-fold coordinated mercury was excluded based on (i) known crystallographic data for binary mercury sulfide, ternary and multi-component mercury(II) thio-compounds of Group VA/15 (P, As, Sb), IVA/14 (Si, Ge, Sn) and IIIA/13 (Al, Ga, In), more than 100 references in the Inorganic Crystal Structure Database (<http://icsd.fiz-karlsruhe.de>). In all these compounds, the mercury coordination was found to be 2 and/or 4. (ii) Our DFT modelling of a 3-fold coordinated Hg-S cluster has also shown its instability (Fig. S5, Supporting information). In future experiments, a mercury-selective local probe, i.e., ^{199}Hg NMR, could be efficient to precise the mercury coordination in glasses.

Additional structural information is available from the detailed analysis of RMC configuration using the RINGS⁵⁷ and the connectivity analysis⁵⁸ codes. The angular distribution functions and mercury connectivity are of primary importance.

Angular distributions. The bond angle distribution $B(\theta)$ is related to the number of bonds between angles of θ and $\theta + \Delta\theta$, and the number of angles available at angle θ is proportional to $\sin \theta$.⁵⁹ Consequently, it is appropriate to remove this effect by plotting the distribution $B(\theta)/\sin \theta$.⁵⁹⁻⁶¹ It should also be noted that the number of angles becomes vanishingly small at $\theta \approx \pi$ and the high- θ part of $B(\theta)/\sin \theta$ appears to be noisy.

Figure 10. (a) A snapshot of the 58.26 Å RMC simulation box with 7600 atoms (Hg, As, S) corresponding to the $x = 0.4$ glass chemical composition; (b) typical RMC generated configurations: (1) isolated $iso\text{-HgS}_{2/2}$ monomer (45.1% of Hg sites) and (2) $(\text{HgS}_{2/2})_2$ dimer (14.8%), (3) isolated $iso\text{-HgS}_{4/4}$ (4.8%) and (4) agglomerated $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_n$ units (28.8%). The remaining oligomeric chains $(\text{HgS}_{2/2})_m$ (5.0%), $2 < m \leq 6$, and connected 4-fold coordinated $(\text{HgS}_{4/4})_n$ units (1.5%) are not shown.

Arsenic-related bond angle distributions, Fig. 12(a) and (b), indicate that $\text{AsS}_{3/2}$ pyramidal geometry is rather well preserved in the $x = 0.4$ glass. Broad asymmetric features at $\approx 96^\circ$ for the two $B(\theta)/\sin \theta$ functions are consistent with characteristic bimodal values for monoclinic orpiment $c\text{-As}_2\text{S}_3$, $\angle\text{S-As-S}$: $96 \pm 3^\circ$ (67 %) and $104.5 \pm 0.5^\circ$ (33 %); $\angle\text{As-S-As}$: $88 \pm 4^\circ$ (33 %) and $102.4 \pm 1.5^\circ$ (67 %),⁵¹ reflecting the C_s symmetry of the $\text{AsS}_{3/2}$ entities. As expected, trigonal units in the glass are more distorted in both intra-pyramidal geometry and inter-pyramidal connectivity.

Figure 11. Simulated partial pair distribution functions $g_{ij}(r)$ for the $x = 0.4$ glass.

Figure 12. Simulated bond angle distributions $B(\theta)/\sin \theta$ for the $x = 0.4$ glass: (a) As-S-As, (b) S-As-S, (c) Hg-S-Hg, and (d) S-Hg-S. The crystal values for monoclinic orpiment are shown by (a) green and (b) light brown bars; (c,d) the characteristic values for trigonal cinnabar are highlighted in red; the tetrahedral values for cubic metacinnabar in yellow. The bar height reflects the expected population of bonds for a given angle.

Mercury sulfide dimorphism in the glass network complicates interpretation of Hg-related angular distributions, Fig. 12(c) and (d). Both two-fold and 4-fold coordinated mercury species seem to be highly distorted. For example, the Hg-S chains in trigonal cinnabar are characterized by well-defined $\angle \text{S-Hg-S} = 173.1^\circ$ and $\angle \text{Hg-S-Hg} = 104.2^\circ$ bond angles.⁵³ The fraction of nearly straight S-Hg-S angles is quite high in the $x = 0.4$ glass, Fig. 12(d). Nevertheless, one observes an additional broad angular distribution with a maximum at $\approx \pi/2$. The Hg-S-Hg angles are more regular. Their narrower distribution is centered at $\approx 110^\circ$, i.e., similar to the crystal value.

Small 4-fold coordinated mercury fraction $f_{\text{Hg}}^{4F} = 0.16$ (RMC) or 0.18 ± 0.02 (direct fitting) makes hardly possible a comprehensive analysis of $\text{HgS}_{4/4}$ tetrahedra using the entire simulation box. A separate examination has been carried out for four-fold coordinated Hg-S entities. Highly

distorted $\text{HgS}_{4/4}$ tetrahedra are mostly observed with a broad distribution of the tetrahedral S-Hg-S angles, i.e., $108\pm 17^\circ$ vs. 109.47° for a regular tetrahedron, and of the Hg-S distances, e.g. 2.40 ± 0.10 Å. Some of $\text{HgS}_{4/4}$ units approach a square geometry with a distribution of the *cis*-angles,⁶² $92\pm 13^\circ$, centered on $\pi/2$ and the *trans*-angles, $148\pm 25^\circ$, similar to π . Some characteristic examples are shown in Fig. S8 (Supporting information). A large variety of 4-fold coordinated mercury species predicted by DFT is thus observed in RMC modelling.

Mercury connectivity. One half of Hg-related entities are only connected to $\text{AsS}_{3/2}$ pyramids, Fig. 10(b). Let's call them isolated units. The majority of isolated Hg-S species (45.1 % of the total number of Hg sites) are two-fold coordinated chain monomers *iso*- $\text{HgS}_{2/2}$. The fraction of isolated four-fold coordinated entities, *iso*- $\text{HgS}_{4/4}$, is just 4.8 % compared to 16 % of $\text{HgS}_{4/4}$ units present within the entire glass network. The *iso*- $\text{HgS}_{2/2}$ and *iso*- $\text{HgS}_{4/4}$ entities are distributed randomly over the network as shows the connectivity analysis.

Plotting the bound mercury fraction $F_{\text{Hg}}(r)^{63}$ for the full RMC model containing 800 Hg atoms as a function of Hg-Hg separation distance, one observes that 95 % of Hg-S species are located within the $r(\text{Hg} - \text{Hg}) \leq 5.3$ Å range from each other (Fig. 13), consistent with the partial pair distribution function $g_{\text{Hg-Hg}}(r)$ (Fig. 11). The calculated value appears to be below the average random Hg-Hg separation distance, 6.3 Å in cubic or 7.8 Å in spherical approximation, highlighted in Fig. 13 in red. This result was expected since one half of Hg-S species are interconnected and the Hg-Hg second neighbor distance is 4.1 ± 0.5 Å. In contrast, 95 % of isolated *iso*- $\text{HgS}_{2/2}$ chain monomers reside within the $r(\text{Hg} - \text{Hg}) \leq 7.2$ Å range supporting a random distribution of isolated Hg-S species.

Figure 13. Bound mercury fraction $F_{\text{Hg}}(r)^{63}$ for the RMC generated 3D structural model of the $x = 0.4$ glass; blue squares: the entire simulation box containing 800 Hg atoms, red diamonds: a partial reduced configuration containing 361 isolated $\text{HgS}_{2/2}$ chain monomers. The derived random Hg-Hg separation distance is highlighted in red spreading out between 6.3 Å (cubic approximation) and 7.8 Å (spherical approximation).

The results also imply that a subnetwork of isolated mercury species is slightly enriched in chain fragments and significantly depleted in 4-fold coordinated Hg entities (−40 %) compared to the mercury speciation over the entire glass network. Consequently, the fraction of isolated $\text{HgS}_{4/4}$ units for the $x = 0.4$ glass appears to be similar to that in the Region 1 glasses, $f_{\text{Hg}}^{4F} \leq 0.1$ at $x < x_0$, Fig. 8(a).

The second half of mercury species form either connected chain fragments $(\text{HgS}_{2/2})_m$, where $m > 1$, or mixed and agglomerated entities including $\text{HgS}_{4/4}$ units, Fig. 10(b). The average chain length is rather small, $m \leq 6$, and the main chain-like fragments are dimers ($m = 2$, 75 % of the total number of $(\text{HgS}_{2/2})_m$ chains). Figure 14(b) shows the fractions of mercury involved in (i) two-fold coordinated Hg-S chains, (ii) mixed and agglomerated $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_{m'}$ entities, and (iii) connected $(\text{HgS}_{4/4})_{m'}$ units plotted as a function of the number of atoms ℓ in a connected structural fragment. For example, the number of atoms in a $(\text{HgS}_{2/2})_3$ trimer is $\ell = 7$, identical to that in a $(\text{HgS}_{2/2})(\text{HgS}_{4/4})$ mixed unit.

Figure 14. Size distribution of connected Hg-S entities of three types for the (a) $x = 0.2$, and (b) $x = 0.4$ glasses: (i) oligomeric chains $(\text{HgS}_{2/2})_m$, $2 \leq m \leq 6$ (red); (ii) mixed agglomerated units $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_{m'}$, $2 \leq m+m' \leq 6$ (blue); (iii) connected tetrahedra $(\text{HgS}_{4/4})_{m'}$, $m' = 2$ and 4 (cyan). The insets show the integrated Hg fraction for the three types of connected Hg-S units.

The $(\text{HgS}_{2/2})_2$ dimers ($\ell = 5$) remain the highest single fraction of connected mercury; however, the population of other members of this family is small. The mixed and agglomerated Hg-S entities also contain up to 6 ($= m+m'$) interconnected $\text{HgS}_{2/2}$ and $\text{HgS}_{4/4}$ units but their size distribution is broader ensuring the next 5 positions in a population ranking. Finally, the minority species appear to be connected tetrahedral fragments.

The inset in Fig. 14(b) shows the summed Hg fraction for the three types of mercury connectivity. The mixed and agglomerated $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_{m'}$ entities appear to be the major species (57.4 %), whose population is by a factor of 1.5 higher than that of the $(\text{HgS}_{2/2})_m$ chains ($m > 1$, 39.5 %). A few connected $(\text{HgS}_{4/4})_{m'}$ units are clearly outsiders (3.1 %).

A preliminary RMC modelling of the $x = 0.2$ glass (Region 1) shows a drastic difference in the mercury connectivity, Fig. 14(a), compared to the $x = 0.4$ glass (Region 2). We note a larger fraction of isolated units *iso*-HgS_{2/2} and *iso*-HgS_{4/4}, 76.5% ($x = 0.2$) vs. 49.9% ($x = 0.4$). The (HgS_{2/2})₂ dimers appear to be the major connected species while the fraction of short oligomeric chains (HgS_{2/2})_m, $2 < m \leq 4$, and (HgS_{2/2})(HgS_{4/4}) mixed units represents just one quarter of connected Hg-S entities. Further detailed analysis of RMC models for the entire HgS-As₂S₃ glass-forming domain will be published elsewhere.

Dual structural role of mercury and the nature of HgS dimorphism in glasses. Two composition domains in (HgS)_x(As₂S₃)_{1-x} glasses below (Region 1) and above $x_0 \approx 0.3$ (Region 2), found using diffraction studies, are consistent with thermal and electronic transport properties: (i) the absence of crystallization peaks at $x \leq 0.3$ in a DSC experiment, and (ii) non-monotonic changes of conductivity parameters with a distinct threshold at $x_0 \approx 0.3$.¹⁵ Crystallization-resistant HgS-poor thioarsenate glasses imply that two-fold coordinated mercury species forming (HgS_{2/2})_m monomers ($m = 1$) and oligomeric chains ($m > 1$), the main Hg-related structural motif in Region 1, are acting as a network-former. The composition trends of the 1.3 Å⁻¹ pre-peak (Fig. 4) also show that the Hg-S chains do not modify significantly the As_nS_n ring size distribution and population. In other words, the chains easily co-exist with AsS_{3/2} pyramids leaving intact local and intermediate-range ordering in the *g*-As₂S₃ host. The dielectric properties of chain-like mercury sulfide (red cinnabar α-HgS is an electronic insulator, $E_g = 2.1$ eV⁶⁴) explain a conductivity decrease and an activation energy increase for the Region 1 glasses.¹⁵

Tetrahedral HgS_{4/4} species behave as a network modifier. They are present in Region 1 but underlying structural hypothesis suggests a random distribution of HgS_{4/4} tetrahedra below

x_0 when $f_{\text{Hg}}^{4F} < 0.1$ and a formation of agglomerated $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_m$ mixed clusters for the Region 2 glasses at $x > x_0$ and $f_{\text{Hg}}^{4F} > 0.1$, Figs. 8 and 10. Similar agglomeration trend was observed for $\text{A}_y\text{Se}_{1-y}$ binary selenide glasses, where A = Si, P, Ge, or As.⁶⁵ Below $y_0 \approx 0.10 \pm 0.02$, $\text{ASe}_{k/2}$ structural units ($k = 4$ for Si or Ge, and $k = 3$ for P or As) are distributed randomly within chain-like selenium network but start forming interconnected A-related subnetwork above y_0 . It should also be noted that the HgS molar concentration $x_0 = 0.30$ corresponds to the Hg atomic concentration $y_0 = 0.073$.

The rigid $\text{HgS}_{4/4}$ tetrahedral fragments are hardly compatible with the hybrid chain/pyramidal network of the Region 1 glasses and crystallization attempts intensify with increasing $x > x_0$ (Fig. 3 in Ref. [15]). The $\text{HgS}_{4/4}$ agglomeration also leads to a fragmentation of the glassy host. A rapid decrease of the $A_{0A}(x)$ amplitude with simultaneous increase of $Q_{0A}(x)$ implies a decreasing population of the As_nS_n rings and their diminished size. In contrast, the $(\text{HgS}_{2/2})_m$ monomers and oligomeric chains are less affected by tetrahedral $\text{HgS}_{4/4}$ species. Their population just stops increasing at $x > x_0$ (Fig. 4) but the intrachain angular distribution, affecting $Q_{0B}(x)$, remains essentially intact.

The increasing population of agglomerated $(\text{HgS}_{2/2})_m(\text{HgS}_{4/4})_m$ mixed subnetwork and increasing tetrahedral $\text{HgS}_{4/4}$ fraction changes the electronic properties. The conductivity starts increasing with corresponding decrease of the activation energy and optical gap (Fig. 6 in Ref. [15]) consistent with semiconducting properties of black cubic metacinnabar β -HgS ($E_g = 0.4$ eV).⁶⁶

The question arises what is the reason of mercury sulfide dimorphism in glasses. Taking into account different thermal stability of trigonal cinnabar α -HgS (stable below 344 °C) and

high-temperature cubic metacinnabar β -HgS, one assumes that in the high-temperature melt mercury species exist as tetrahedral units $\text{HgS}_{4/4}$ (no structural information is available for liquid HgS). Quenching the $\text{HgS-As}_2\text{S}_3$ glass-forming melt, $\text{HgS}_{4/4}$ tetrahedra are entirely or partially transformed into $(\text{HgS}_{2/2})_m$ chain fragments. The mercury transformation on cooling implies a significant distortion of both two-fold and 4-fold coordinated mercury species observed in RMC modelling and predicted by DFT simulations. The transformation rate seems to be dependent on stoichiometry relations $\text{HgS/As}_2\text{S}_3 = x/(1-x)$ and increases with decreasing x . Metastable at room temperature, frozen β -HgS, observed for the $x = 0.5$ neutron sample, is consistent with this hypothesis. Further studies of $\text{HgS-As}_2\text{S}_3$ liquids are necessary to elucidate the nature of mercury sulfide dimorphism in glasses.

CONCLUSIONS

Pulsed neutron and high-energy X-ray diffraction of mercury thioarsenate glasses $(\text{HgS})_x(\text{As}_2\text{S}_3)_{1-x}$, $0.0 \leq x \leq 0.5$, combined with DFT simulation of four-fold mercury species and RMC modelling of high-resolution diffraction data were used to unveil short- and intermediate-range ordering of these exciting vitreous materials of practical importance. Mercury sulfide appears to be dimorphous over the investigated composition range. The main structural motif consists of $(\text{HgS}_{2/2})_m$ monomers ($m = 1$) and oligomeric chains ($2 \leq m \leq 6$) forming a hybrid Hg-S chain/As-S pyramidal network. The two-fold coordinated mercury is thus a network former. The population of 4-fold coordinated $\text{HgS}_{4/4}$ minorities increases with x but even at the glass-forming limit, $x = 0.5$, the fraction of four-fold coordinated mercury is below 50%, i.e., $f_{\text{Hg}}^{4F} \approx 0.3$. The highly distorted tetrahedral mercury species behave as a network modifier. Two

composition domains have been found in the HgS-As₂S₃ glasses with a threshold concentration $x_0 \approx 0.3$. In mercury-poor glasses (Region 1, $x < x_0$), the HgS_{4/4} units seem to be distributed randomly in the hybrid network and do not affect structural, thermal or electronic properties. An agglomerated mixed (HgS_{2/2})_m(HgS_{4/4})_m subnetwork is formed in HgS-rich vitreous alloys (Region 2, $x > x_0$, $f_{\text{Hg}}^{4F} > 0.1$), leading to a fragmentation of the host network, reduced thermal stability and crystallization as well as changes in electronic properties. The nature of mercury sulfide dimorphism in glasses appears to be related to a polyamorphic transformation during glass synthesis and quenching. Further studies of high-temperature HgS-As₂S₃ liquids will give a detailed and definitive answer.
