Physics-based Computer Simulation of the Long Term effects of Cardiac Regenerative Therapies

Lee, L.C. Sundnes, J.S. Genet, M. Wall, S.T.

June 10, 2015

Abstract

We describe the application of a computational model of left ventricular (LV) electromechanics, growth and remodeling to simulate the long term effects of cardiac regenerative therapies. The model is based on coupling a biophysically detailed model of short term cardiac electrophysiology and mechanics, to a model framework capable of predicting growth and remodeling over a longer time scale. The simulation considers two distinct concurrent and clinically relevant phases, namely, remodeling induced by a myocardial infarction, and the long term response following regenerative therapy to treat the infarct. Model predictions show post-infarct LV enlargement (hypertrophy) that is driven by abnormal strain values surrounding the infarct. Regenerative therapy tends to normalize the myofiber strain values and results in a reduction of LV size. These findings are consistent with experiments and clinical studies.

1 Introduction

Heart failure (HF) continues to pose a significant burden on our society. Between 2010 to 2030, the real cost of HF is projected to increase by a staggering 200%¹². Among all HF conditions, 70% of them are of systolic origin, with coronary artery diseases (CAD) accounting for approximately two thirds of these cases⁴⁰. In the event of myocardial infarction in adult mammals, cardiomyocytes, unlike other cells, do not regenerate sufficiently to replace the lost ones and the end result is a permanent loss of contractile function in the infarcted region.

Current standard therapy for treating myocardial infarction (MI) includes pharmacological treatments such as the administration of thrombolytic agents to restore coronary blood flow and angiotensin converting enzyme inhibitors to reduce blood pressure². The long-term prognosis of MI remained poor. Although current treatments have improved MI survival dramatically, around 24% of MI survivors progress to develop HF⁴¹ that has limited treatment options. To address this issue, a myriad of new devices and treatments for MI have been developed in recent years including, for instance, surgical ventricular restoration⁴, ventricular partitioning device³⁰, and cardiac regenerative therapies^{6,48}.

Among these treatments, cell-based cardiac regenerative therapies have garnered a considerable interest lately and multiple strategies to regenerate diseased hearts are currently

under investigation. These strategies include the direct transplantation of stem cells into the infarcted myocardium, and the reprogramming of residing non-myocytes to cardiomyocytes in the diseased heart⁶. A number of clinical and experimental studies on these regenerative therapies have shown favorable post-treatment outcome in the form of attenuation or reversal of adverse myocardial remodeling^{31,45}. The same positive outcome was, however, not found in other studies²⁸. A better understanding of the effects of cardiac regenerative therapies is, therefore, very much needed before they can be applied optimally to treat MI.

Computational modeling has been used to develop an understanding of heart disease treatments^{20,25,26,42,44} and offers a useful and efficient way to understand the effects and mechanisms of treatments²². While most computational models of the heart are limited to simulating the immediate acute effects resulting from a treatment, recent advancement in theory and model development have led to an emerging class of computational models that can describe the long term cardiac remodeling process^{10,17,21}. Although this branch of modeling is an emerging field and all models are fairly recent, a number of these models have been used to evaluate the long term effects of HF and treatments^{16,18}.

Here, we utilized a recently developed electromechanics-growth model²³ to simulate the long-term effects of cardiac regenerative therapies. This growth model was established previously based on the principle that myocytes undergo hypertrophy or atrophy in order to restore strain homeostasis²¹. Simulations using this model has shown that the collective behavior of myocytes in response to global mechanical loading and unloading results in, respectively, the dilation and shrinkage of the left ventricle (LV). This feature was found in hearts that have been implanted with a left ventricular assist device⁵. By applying this model to simulate the effects of cardiac regenerative therapies, we seek to test whether the model prediction is consistent with those found in experiments and clinical studies. Doing so will also enable us to understand how the surviving cardiomyocytes in the non-infarcted region respond collectively to the regional restoration of tissue contractile function at the infarct where new myocytes are introduced. Upon calibration with experimental studies and clinical data, this model will enable us to gain a deeper insight into the mechanism of cardiac regenerative therapies.

The paper is organized as follows. In Section 2, we briefly outline the electromechanics-growth model and describe details of the simulation setup. Section 3 presents the simulation results while the findings and limitations are discussed in Section 4. Finally, we summarize our findings and present preliminary conclusions in Section 5.

2 Methods

2.1 Electromechanical-growth model

The electromechanics-growth model is described in details in Lee et al.²³. Briefly, the model is an integration of a cardiac growth constitutive model²¹ with a cardiac electromechanics model³⁸. Long term cardiac growth was described in the model using the theoretical framework in which the deformation gradient tensor $\mathbf{F}$ was multiplicatively decomposed into a growth tensor $\mathbf{F}_g$ and an elastic deformation tensor $\mathbf{F}_e$, i.e., $\mathbf{F} = \mathbf{F}_e \cdot \mathbf{F}_g$ ³⁴. A constitutive relationship was prescribed for $\mathbf{F}_g$, so that growth and reverse growth occurs only along the cardiomyocyte long axis, and only if the myocyte stretch is outside of a prescribed interval

of homeostatic stretch values. No growth occurs if the myocyte stretch stays within the prescribed homeostatic interval. This constitutive relation was formulated based on previous experimental studies showing that (1) volume overload in ischemic cardiomyopathy causes cardiomyocytes to become elongated⁹ and (2) this behavior can be reversed upon removal of the overloading conditions^{8,14}.

On a shorter timescale, cardiac electrophysiology (EP) was described using the standard bidomain equations and a cellular EP model⁴⁷; and cardiac mechanics was described with a passive material model¹¹ and an active contraction model³³. The electromechanical behavior of the heart is described by coupling these models³⁸.

Because the cardiac growth model²¹ and the electromechanics model³⁸ operate at two different timescales, i.e., growth and remodeling becomes appreciable only after a large number of heart beats, a separation of timescale was invoked to integrate the two models. Two assumptions are essential for the separation of time scales. The first assumption is that growth and remodeling occurs too slowly to be detectable on the time scale of a single heart beat. Correspondingly, the growth tensor $\mathbf{F}_g$ remains constant within a cardiac cycle in our simulation. The second assumption is that the stimuli that drive growth and remodeling can be derived from a representative cardiac cycle. The simulation of a cardiac cycle then becomes equivalent to that of a “growth cycle” within which growth and remodeling is not detectable and does not affect the electromechanics of the heart. By invoking these assumptions, the growth tensor is updated once for every cardiac cycle, which enables us to prescribe the time-average stretch over a cardiac cycle as the stimulant for cardiomyocytes growth¹³.

2.2 Left ventricular geometry

The electromechanics-growth model was applied to a human left ventricular geometry that was reconstructed from magnetic resonance images⁷. Three distinct regions were prescribed in the LV, namely, (i) the infarct, (ii) the borderzone and (iii) the remote (healthy) regions.

Figure 1: Schematic of the left ventricular infarct model and myofiber orientation color coded with the prescribed myofiber helix angle.

These regions differ from each other only in terms of the prescribed tissue contractility, a material parameter that is denoted by the “reference tension” in the active contraction model³³. The infarct was assumed to be devoid of cardiomyocytes and was prescribed to be non-contractile. On the other hand, the borderzone region was prescribed to have one-half the contractility of the remote region as direct active force measurements on cardiomyocytes taken from the borderzone were found to have depressed contractility³⁶. The helix angle that defines the cardiomyocytes long-axis was prescribed to vary linearly across the myocardial wall from -60° (endocardium) to 60° (epicardium) in the entire LV based on previous histological studies³⁷(**Figure 1**). The LV model was coupled to a 3-parameter Windkessel model to simulate the ejection phase in a cardiac cycle. The regional homeostatic cardiomyocytes stretch was obtained from the solution for the time-average stretch over a cardiac cycle $\bar{\lambda}_e$ in the same LV model with normal contractile function where the infarct and borderzone have contractilities equal to that in the remote region. Standard finite element method was used to solve the LV computational model. More details and all the parameters associated with the model can be found in Lee et al.²³.

2.3 Simulation protocol

To simulate the effects of cardiac regenerative therapies via the introduction of new contractile cardiomyocytes into the myocardium, the following two-phase simulation protocol was implemented. First, in the remodeling phase, the model was run for 5 growth cycles with impaired contractility in the infarct and borderzone. Then, the post-treatment phase was simulated by restoring infarct and borderzone contractility back to their normal values and running the model for another 10 growth cycles. Because the focus here is on growth and reverse growth due to cellular hypertrophy and atrophy of the residing cardiomyocytes, respectively, the infarct, which was assumed to be devoid of cardiomyocytes, is prohibited from growing.

3 Results

3.1 Pressure-volume relationship

Our simulation results show a right shift of the pressure-volume (PV) loop during the first 5 cycles when a non-contractile infarct and a borderzone with depressed contractility are present in the LV. Compared to the LV with normal contractile function which has an ejection fraction (EF) of 49%, the infarcted LV shows a substantially smaller PV loop in the first cycle (EF = 32%) that shifts towards the right in the next 4 cycles (EF at cycle 5 = 26%).

Restoration of the infarct and borderzone contractilities back to the normal values in the post-treatment simulation phase led to an expected larger PV loop, with EF = 47%. In subsequent cycles, the PV loop shifts towards the left (**Figure 2b**) and the EF was maintained in these cycles.

Figure 2: Pressure-volume loop (a) remodeling phase and (b) post-treatment phase.

3.2 Geometrical changes

The shifting of PV loops is reflected by a change in the LV geometry. During the remodeling phase, the LV became more dilated and spherical (**Figure 3a**). The growth magnitude was measured by the determinant of the growth tensor i.e., $\det \mathbf{F}_g$. Growth of the LV occurs primarily at the borderzone as indicated by the larger values of $\det \mathbf{F}_g$ in that region. This growth results from a lengthening of the cardiomyocytes in the infarct borderzone.

During the post-treatment phase, the growth process was reversed and the LV became

Figure 3: Geometrical changes of the LV during (a) remodeling and (b) post-treatment phases. Leftmost: LV end-diastolic configuration at (a) cycle 5 (red) superimposed to that at cycle 1 (grey) and (b) cycle 15 (blue) superimposed to that in cycle 6 (red). Middle: Determinant of growth tensor $\det \mathbf{F}_g$ at (a) cycle 5 and (b) cycle 15. Rightmost: corresponding long and short-axis view. Black lines in these views denote the same cross section at the beginning of the two simulation phases. Note: $\det \mathbf{F}_g$ is prescribed to remain constant at 1 in the infarct.

progressively smaller and more ellipsoidal (**Figure 3b**). Correspondingly, the growth magnitude $\det \mathbf{F}_g$ decreases at the borderzone, reflecting the shortening of cardiomyocytes in its longitudinal axis.

3.3 Myofiber stretch

At the beginning of the remodeling phase (cycle 1), the time-averaged elastic myofiber stretch $\bar{\lambda}_e$ is higher at the infarct and borderzone compared to that found in the normal LV (**Figure 4**). In subsequent cycles during this phase, $\bar{\lambda}_e$ decreases in the borderzone and approaches that found in the normal LV. With growth (cycle 1 – 5), however, $\bar{\lambda}_e$ decreases in the borderzone and approaches that in the normal LV. At the infarct, which was prescribed not to grow, the time-averaged elastic myofiber stretch did not decrease but increased slightly during the remodeling phase. We note that the reason why $\bar{\lambda}_e$ is highest at the infarct is because the infarct did not contract and underwent stretching even during systole.

In the post-treatment phase, contractility was restored at the infarct and borderzone and the immediate effect (in cycle 6) was a reduction of $\bar{\lambda}_e$ in these regions. The reduced values are below the corresponding homeostatic values found in the normal LV. In subsequent cycles of the post-treatment phase, the time-averaged elastic myofiber stretch in the borderzone and infarct increased and approached their respective homeostatic values.

Figure 4: Left: time-average myofiber stretch $\bar{\lambda}_e$ at the infarct, borderzone and remote regions in the two simulation phase. Right: myofiber stretch taken at arbitrary points from each of these regions. (Same color scheme applied here). Note that: infarct and borderzone were regenerated at the end of cycle 5.

4 Discussion

Although computational models have been used to simulate the long term effects of heart diseases and therapies^{10,18,32}, most of these models are only capable of simulating growth

based on standard time points in the cardiac cycle (e.g., end-of-diastole or end-of-systole). As such, time-averaged, minima or maxima of local deformation signals, which were found to be likely candidates for driving hypertrophy¹³, cannot be applied in these models as growth stimulant. Here, we have used the time-averaged myofiber stretch as the growth stimulant and have, for the first time, applied the electromechanics-growth model to simulate the effects of cardiac regenerative therapies. Our simulation results show features that are generally consistent with experimental and clinical studies, both in the remodeling and reverse remodeling phase.

4.1 Remodeling phase

During the remodeling phase, our model predicts that the time-average myofiber stretch becomes higher in the borderzone and infarct than that found in the normal LV (**Figure 4**). Therefore, growth occurs mostly in the borderzone and the LV becomes dilated and more spherical as a result (**Figure 3**). Globally, the LV dilation is manifested by a shifting of the PV loop towards the right (**Figure 2**).

All these features are consistent with experimental and clinical studies both at the cellular and organ level. First, abnormal stretch in the form of a reduced contractile deformation during systole is a widely observed feature in the borderzone after MI^{3,19}. Correspondingly, cardiomyocytes in the borderzone region would, when averaged over a cardiac cycle, undergo higher stretching. Second, cardiomyocytes in the borderzone of animal MI models have displayed appreciable hypertrophy when compared to those at remote region^{15,36}. For example, cardiomyocytes cross sectional area was found to be about 70% higher than that in the remote region 2 weeks after MI in sheep hearts³⁶ whereas isolated cardiomyocytes from explanted human hearts with ischemic dilated cardiomyopathy were measured to be about 40% longer than those found in normal heart⁹. Third, at the organ level, progressive LV dilation, in the form of a parallel increase in both end-diastolic volume and end-systolic volume that results in a right shift of the PV loop is a pathophysiological feature of MI that is found in both humans and animals^{29,39}.

4.2 Post-treatment phase

Restoration of the infarct and borderzone contractility to their normal values in our simulation led to an immediate increase in both stroke volume and EF. The time-average myofiber stretch also decreases immediately and fell below their corresponding homeostatic values in the infarct and borderzone (**Figure 4**). As a result, cardiomyocytes in the borderzone growth was predicted by our simulation to undergo atrophy and growth was reversed during the post-treatment phase (**Figure 3**). This reversal is manifested globally by a decrease in the LV size that is associated with the shifting of PV loop towards the left (**Figure 2**).

Because the effects of cardiac regenerative therapies are still not widely established, and at times, controversial³⁵, it is difficult to assess, with certainty, that our model predictions agree with the features found in experiments and clinical studies of this class of therapies. Nevertheless, it is worthwhile to discuss our model prediction in the context of some these studies. In general, cardiac regenerative therapies have been found to be effective in improving long term cardiac function^{31,46}, although other studies have found the contrary to

be true²⁷. Studies that found positive effects in this treatment have shown that the introduction of new contractile cardiomyocytes can attenuate³¹ or even reverse⁴⁶ the remodeling process associated with MI. Specifically, *in vivo* reprogramming of fibroblasts into contracting cardiomyocytes-like cells in a murine infarct model led to an increase in stroke volume and ejection fraction³¹. Similarly, intramyocardial injections of bone marrow progenitor cells into the infarct and borderzone of MI patients was found to lead to significant reverse remodeling where both EDV and ESV were decreased by 20% at 1 year follow up⁴⁶. These findings are consistent with our model predictions.

Besides functional change at the global level, postmortem analysis in porcine hearts implanted with mesenchymal stem cell (MSC) have also found that the cardiomyocytes in the sub-endocardial rim of the MI are not hypertrophied when compared to those taken from the remote region¹. It is unclear, however, as to whether these unhypertrophied cardiomyocytes are proliferated endogeneous cardiomyocytes or newly differentiated cardiomyocytes. Irrespective of this result, our model prediction suggesting that hypertrophy will regress in the cardiomyocytes at the infarct and borderzone upon restoration of the tissue contractility is consistent with this finding.

4.3 Limitations

There are several limitations associated with this study. First, we did not consider the effects of infarct expansion, which are events that occur early in the course of MI that lead infarct thinning⁴³. Second, we did not take into account that the borderzone can extend itself during the remodeling¹⁵. Although the borderzone in our simulation expands in size via cellular hypertrophy, this effect is different from the extension of borderzone width via the recruitment of previously healthy myocardium into this dysfunctional zone. Last, we did not take into account the immediate increase in LV wall volume after injection of new cells or retroviral particles that some of these cardiac therapies were based on. Although the injected volume is small compared to the LV wall volume in some studies (e.g., 2.5 ml injection vs. LV wall volume of ~ 150 ml⁴⁶), there are other studies in which the injected volume is significant (e.g. 15 ml injection vs. LV wall volume of ~ 50 ml¹). As shown in a number of modeling studies, injection of new non-contractile materials into the LV wall can have an immediate impact on the regional mechanics that would affect the remodeling process^{24,42}.

5 Conclusion

In summary, we have applied a recently developed computational model to simulate the long-term effects of cardiac regenerative therapies and have shown that the model is able to predict a number of features found in clinical and experimental studies. For the model to be quantitatively accurate, appropriate refinement and calibration with longitudinal studies involving animal models and patient data is necessary. Our future studies will focus on this aspect.
