RESEARCH LETTER

10.1002/2014GL063013

Key Points:

- Enceladus' ocean is modeled as a subglacial lake
- The conditions in Enceladus' internal ocean are met for production of clathrates
- Efficient trapping of methane reduces its abundance below plume levels

Abstract The internal ocean of Enceladus can be expected to present conditions favorable to the trapping of volatiles in clathrates. This process could influence the eventual composition of the ocean and therefore of the plumes emitted by the south polar region. Here we used a statistical thermodynamic model to assess which species detected in the plumes by the Cassini-Ion and Neutral Mass Spectrometer experiment are trapped in clathrates. We treated Enceladus' internal ocean as a terrestrial subglacial lake with a mixture of dissolved volatiles indicated by plume gas measurements. We find that the conditions for clathrate formation are met in this ocean, except above 20 km or in hypothetical hot spots. The formation of multiple guest clathrates depletes methane below plume levels, suggesting that clathrates eventually dissociate (releasing methane) in the fissure that connects the ocean to the surface or that another mechanism (such as hydrothermal reactions) is compensating by adding methane into the ocean.

1. Introduction

Since the detection by the Cassini spacecraft of the gas emission of plumes by Saturn's moon Enceladus [Dougherty *et al.*, 2006; Porco *et al.*, 2006; Waite *et al.*, 2006], the possibility of an internal ocean has been suggested, gaining more support as data were gathered and interpreted [Postberg *et al.*, 2009, 2011; less *et al.*, 2014]. In order to understand the processes in the interior of Enceladus, it is necessary to determine how representative the composition of the plumes is of the ocean. In this letter we investigate how the production of clathrate hydrates could impact an ocean with dissolved volatiles in the proportions detected in the plumes.

Enceladus' ocean is expected to feature a combination of conditions favorable to clathrate production: availability of large quantities of water, low temperature in the interior, high pressure, and presence of species with high propensity to being trapped in clathrate, such as methane [Sloan and Koh, 2008]. Furthermore, the trapping of species into multiple guest clathrates could alter their proportion in the ocean, since not all species would be equally depleted. Finally, trapping in clathrate is a likely process to explain possible noble gas deficiencies in planetary environments [Mousis *et al.*, 2011, 2013a].

Section 2 gives an overview of the statistical thermodynamic model used in this study and the assumptions used as our starting point. It also discusses the selection of the species to be investigated and the conditions in the ocean. Section 3 presents the results of the calculations. Section 4 is devoted to discussion and conclusions.

2. Ocean Model

2.1. Subglacial Lake Model

In this study, we apply to Enceladus' internal ocean the approach used by Mousis *et al.* [2013b] to depict the time evolution of Lake Vostok's composition on Earth. It is based on a thermodynamic statistical model giving the abundances of species dissolved in the ocean, and the proportions of guests trapped in clathrate, produced at each time step. We refer the reader to the aforementioned paper for further information on the model itself.

We assume the existence of a process continuously bringing gases to the ocean; if Enceladus' ocean is considered in a steady state, the expulsion of volatiles with the plumes implies a gas input. We consider continual melting/freezing of the surrounding ice, releasing trapped volatiles or bubbles of gas, with

Table 1. Cassini Measurements in Enceladus' Plumes^a

Species	Mixing Ratio	X/H ₂ O	x_K^{gas}	x_K^{comet}
H ₂ O	0.87	1	1	
H ₂	0.11	0.126		
CO ₂	5.2×10^{-3}	5.98×10^{-3}	0.399	0.23
CH ₄	1.9×10^{-3}	2.18×10^{-3}	0.133	0.06
NH ₃	6.1×10^{-3}	7.01×10^{-3}		
CO	$\leq 6.4 \times 10^{-3}$	7.36×10^{-3}	0.233	0.46
N ₂	$\leq 6.1 \times 10^{-3}$	7.01×10^{-3}	0.233	0.18
HCN	$\leq 1.2 \times 10^{-3}$	1.38×10^{-3}		
H ₂ S	2.1×10^{-5}	3.26×10^{-5}	2.17×10^{-3}	0.06
Ar	N/A	N/A	1.5×10^{-2}	1.5×10^{-2}
Kr	N/A	N/A	9.0×10^{-6}	9.0×10^{-6}
Xe	N/A	N/A	8.8×10^{-7}	8.8×10^{-7}

^aAll data are from slow flybys E14, E17, and E18, except H₂S (flyby E7). Fourth column shows proportion in the mixture used in our model. Last column is the proportions for an alternative composition (comet-like). Species not likely to form clathrate have been excluded.

convection in the crust ensuring availability of volatiles at the water/ice interface (conditions for convection are discussed in *Behoukova et al.* [2013] and can reasonably be assumed to be met at least at some periods of Enceladus' life); hydrothermal activity could also factor in. The exact process of addition does not affect the conclusion.

With time, the gas dissolved in the ocean reaches a partial pressure sufficient to trigger clathrate formation. Steady state is attained when the mole fractions of volatiles species withdrawn by clathrates from the ocean are similar to those delivered to the ocean.

Parameters used in the model are given in *Mousis et al.* [2013a] and *Sloan and Koh* [2008].

The time step of the model is the time needed to add a given quantity of gas per unit volume of the ocean; this quantity is arbitrary as we are interested in the steady state eventually reached.

The initial mixture of volatiles in the ocean is similar to the one continuously added. We refer section 2.2 for the choice of volatiles considered.

2.2. Choice of Species

Species to be incorporated in our calculations meet two criteria: (i) they are among the most abundant ones detected in the plume, and (ii) they can be entrapped in clathrates. Results of Cassini measurements in Enceladus' plumes for the most abundant species are listed in Table 1. Because there is an ambiguity in measurement between N₂ and CO at mass 28 [*Waite et al.*, 2009], we know the N₂ + CO abundance but not the actual proportion of those two species. C₂H₄ could also contribute to mass 28, but the common interpretation is that CO and N₂ are prevalent; moreover, there is no data on trapping of C₂H₄ in clathrates. Here we assumed an equal repartition between CO and N₂ in our calculations. This puts N₂ at 0.35% relative to H₂O, consistent with the measurements of Ultraviolet Imaging Spectrograph establishing an upper value at 0.5% [*Hansen et al.*, 2011]. This results in a mixture composed of CO, CO₂, CH₄, N₂, and H₂S as they have been reliably measured during the multiple flybys of Enceladus by Cassini. The mole fractions of the species included in the mixtures used in our model are given in Table 1. We have also added the heavy noble gases Ar, Kr, and Xe to the mixture in order to track their evolution. The chosen noble gas abundances relative to H₂O correspond to Ar/O, Kr/O, and Xe/O ratios derived from the solar abundances given in *Mousis et al.* [2008]. Argon and Krypton have not been firmly detected by Cassini-Ion and Neutral Mass Spectrometer (INMS), which makes the examination of any possible cause of their depletion valuable. Xenon is out of the mass range of INMS, and any conclusion about its depletion would have to be confirmed by other, future means.

We first used a mixture of volatiles directly following the INMS measurements of the plumes (next to last column of Table 1). The proportion of species in the plume mixture does not allow us to infer the structure of clathrate (Structure I or Structure II) that could be formed in the ocean. While CO and CO₂ are both known to form Structure I clathrate [*Sloan and Koh*, 2008], N₂ is prone to form Structure II structures. Moreover, the ambiguity of measurements between CO and N₂ means that the mixture could be as well dominated by Structure I-forming or Structure II-forming species. We, therefore, show and discuss results for both cases.

An alternative and more hypothetical volatile composition has also been considered, based on cometary volatiles from Hale-Bopp [*Bockelée-Morvan et al.*, 2004]. The mole fraction derived from the nucleus production is given in the last column of Table 1.

Figure 1. Effect of temperature and composition on the dissociation pressure of clathrates. The two horizontal dashed lines correspond to the column pressure integrated down to 35 km depth (bottom line) and 50 km depth (top line).

ice/ocean interface. Lower temperatures may be envisioned for a liquid ocean due to the presence of NH_3 , but without any firm constraint on its abundance the exact value would only be a guess. Similarly, it is very possible that some parts of the ocean are far hotter (at least up to ~ 373 K), but this could be limited to hot spots [Matson *et al.*, 2007; Hsu *et al.*, 2014]. Figure 1 displays the dissociation pressure of clathrates computed in the 273–373 K range against column pressures integrated down to several depths. It shows that (i) the variations in clathrate composition only have a small effect on the dissociation pressure and (ii) this effect is negligible at the lowest temperatures that are expected to dominate in the major part of the ocean. Figure 1 also shows that clathrate formation is plausible in the ocean. The vertical extension of the ocean has been constrained by gravimetric measurements, which suggest that the rock/ocean and ice/ocean interfaces are at ~ 50 km (~ 5.3 MPa) and 35–40 km (3.6–4.2 MPa) depths, respectively [Jess *et al.*, 2014]. At ~ 273 K, clathrate

2.3. Conditions of Pressure and Temperature

Pressure and temperature in the ocean are critical factors for clathrate formation and storage. We, therefore, have assessed the dissociation pressure of clathrates featuring the guests determined in section 2.2 (for plume-like composition), depending on a plausible range of temperature, and compared the results to the expected conditions in the ocean. To account for the ambiguity between CO and N_2 in the clathrate composition, the calculations have been performed for three cases: CO and N_2 abundances being equal (nominal case), CO being absent in favor of N_2 , and N_2 being absent in favor of CO.

In Matson *et al.* [2012], a temperature of 273.15 K is assumed, which is the most plausible choice, especially near the

formation requires a pressure of ~ 2.2 MPa, corresponding roughly to a depth of 22 km, well above the expected ice/ocean interface. On the other hand, temperatures above 300 K would prevent clathrate formation (and trigger their dissociation) as the dissociation pressure would exceed the pressure expected at the ocean's bottom. The layout considered for the study is summarized in Figure 2.

The conditions are therefore present in all the ocean for clathrate to form. Their subsequent fate, however, depends on a number of factors. Depending on their density, they may ascend to the ice/ocean interface or sink to the bottom of the ocean. In the former case, they would form a clathrate layer at the interface, in the latter, they could

Figure 2. Layout of Enceladus' ocean and ice crust considered for this study. Yellow line shows the depth above which clathrates hosting plume species are not stable. Clathrate formation is susceptible to occur at any point of the ocean where pressure and temperature conditions are met.

Figure 3. Considering a gas input based on plumes: Mole fractions of N_2 , CO_2 , CH_4 , CO , H_2S , Ar , Kr , and Xe dissolved in the (left) ocean and trapped into (right) clathrates and expressed as a function of time units. Solid and dashed lines represent formation cases of Structures I and II clathrates, respectively.

be dissociated by high temperatures caused by hydrothermal activity, the exact result depending on the distribution of heat (homogeneous or punctual “hot spots”).

3. Results

We have computed the density of clathrates formed (assuming a volatile input based on plumes) following the approach of *Sloan and Koh* [2008], assuming that their cages are fully filled. These clathrates may exist in Structure I or II, namely the two most widespread clathrate structures in natural environments. We found densities of 1.04 and 0.97 for Structures I and II clathrates, respectively. We have then compared those values to the density of sea salt water at high pressure, which is close to 1.030 in the 3.6 to 5.3 MPa range (35–50 km depth), a value calculated with the Computer Support Group (CSG) Water Density Calculator, based on the equation of *Millero et al.* [1980]. We then conclude that Structure II clathrates would ascend in the ocean, even if the cages are fully filled. On the other hand, the behavior of Structure I clathrates is more uncertain since their density is very close to the ocean’s value. Given the large uncertainties concerning the ocean’s composition and the fact that the density of Structure I clathrates could be lower if the cages were partly filled, we cannot derive any firm conclusion about their fate in the ocean. It is still possible that some Structure I clathrates may ascend in the ocean.

Figure 3 shows the evolution of the mole fractions of species dissolved in the ocean and trapped in clathrates as a function of time using a volatile mixture based on the plumes, measured by Cassini INMS. The calculations have been performed at 5 MPa (close to 50 km depth). Additional calculations show negligible variations if they were performed at different pressures (e.g., 10 MPa). Among the various species, all compounds except CO_2 undergo depletion in the ocean with time. Methane depletion is especially noticeable. Figure 4 shows the evolution when using a cometary volatiles mixture. Similarly, methane is depleted below plume levels. It is also interesting to note that H_2S stays at much higher levels than in the plume, implying a consumption process, such as sulfide formation at the water-rock interface.

Alternative input compositions have been tried to match the species final abundance with plumes composition: while this could be accomplished for other species, it proved to be impossible with methane. We can, therefore, conclude that clathrate formation efficiently depletes methane below measured plumes levels, implying that methane is not in equilibrium, due to a recent release or clathrate disruption. It also appears that, among noble gases, xenon is depleted by 1 order of magnitude in both Structures I and II.

Figure 4. Considering a gas input based on comet Hale-Bopp: Mole fractions of N_2 , CO_2 , CH_4 , CO , H_2S , Ar , Kr , and Xe dissolved in the (left) ocean and trapped into (right) clathrates and expressed as a function of time units. Solid and dashed lines represent formation cases of Structures I and II clathrates, respectively.

Krypton undergoes a stronger depletion in the Structure II case than in the Structure I case, and argon is almost unaffected in the Structure I case and depleted by 1 order of magnitude if Structure II formation is assumed.

4. Discussion and Conclusions

The conditions for volatile clathration are present in Enceladus' ocean. We can, therefore, assume that multiple guest clathrates featuring some of the species detected in the plumes are formed. The most striking result is the efficient depletion of methane. The proportions between volatiles measured in the plumes are not possible in a saturated ocean, as methane would be strongly depleted due to its trapping in clathrate. To match the plume's composition, this implies subsequent dissociation of the clathrate (releasing methane) or that methane is supersaturated in the ocean due to fast addition (hydrothermal activity). After ascension to the top of the ocean, clathrates could form a layer at the ice/ocean interface. Hydrostatic considerations indicate that water in vents will raise up to 90% of the ice crust thickness (i.e., 3.5 km below the surface; other mechanisms are necessary to create plumes); depending on the kinetic of their dissociation, clathrates could reach this height and their eventual dissociation would increase pressure and participate in plumes creation and enrichment in volatiles.

The methane content of the plumes has not noticeably changed since their detection, implying that the related processes are steady over a several years time scale. If the time scales of trapping in clathrates and of transfer throughout the ocean are shorter, this would strongly point to a steady methane production at approximately the plumes' ejection rate. The experimental methane entrapping rates [Gainey and Elwood Madden, 2012], applied to the surface of the South Polar Region, suggest a yearly methane entrapping that is 40,000 times the amount of methane ejected in the plumes (assuming a plume rate of 350 kg/s) over the same time scale. Additionally, numerical simulations for Europa's internal ocean [Goodman and Lenferink, 2012] indicate that hydrothermal activity generates ascending currents at a speed of 1–5 cm/s, giving a transfer time scale well below a year. Dedicated simulations are required to ascertain how this can be transposed to Enceladus, as a faster rotation rate may impact upward currents [Aurnou et al., 2008].

Therefore, an explanation of the processes in Enceladus' ocean, which ultimately leads to the production of the plumes, must include the trapping of volatiles in clathrates as a factor, as it alters the composition of the ocean and can be involved in creating the conditions for the observed plumes.
