(Received 23 January 2017; published 18 April 2017)

We compare the optical absorption of extended systems using the density-density and current-current linear response functions calculated within many-body perturbation theory. The two approaches are formally equivalent for a finite momentum $\mathbf{q}$ of the external perturbation. At $\mathbf{q} = \mathbf{0}$, however, the equivalence is maintained only if a small q expansion of the density-density response function is used. Moreover, in practical calculations, this equivalence can be lost if one naively extends the strategies usually employed in the density-based approach to the current-based approach. Specifically, we discuss the use of a smearing parameter or of the quasiparticle lifetimes to describe the finite width of the spectral peaks and the inclusion of electron-hole interaction. In those instances, we show that the incorrect definition of the velocity operator and the violation of the conductivity sum rule introduce unphysical features in the optical absorption spectra of three paradigmatic systems: silicon (semiconductor), copper (metal) and lithium fluoride (insulator). We then demonstrate how to correctly introduce lifetime effects and electron-hole interactions within the current-based approach.

I. INTRODUCTION

The electromagnetic linear response of solids can be measured experimentally by applying a small external perturbation, or probe, which induces a small change in the sample material. This change is the response of the material to the perturbing field and it can have both longitudinal and transverse components, depending on the experimental setup and the inhomogeneity of the system. Well-known examples of such experiments are the measurements of absorption, electron energy loss, Kerr and Faraday effects, and dichroism.

From the theoretical point of view the linear response of a system to longitudinal fields can be obtained from both the density-density response function $\chi_{\rho\rho}$ and the current-current response function $\chi_{\underline{j}\underline{j}}$, which is a tensor [1]. Instead, the response to transverse fields can only be described using $\chi_{\underline{j}\underline{j}}$. This is due to the fact that the density determines the longitudinal current—through the continuity equation—but not the transverse current. An important instance where transverse electric fields come into play is the recent experimental progress on topological insulators [2,3]. Therefore approaches based on $\chi_{\underline{j}\underline{j}}$ are more general than those based on $\chi_{\rho\rho}$. On the other hand, the current-density based approach is more susceptible to numerical issues and instabilities. For example, the paramagnetic and diamagnetic contributions to $\chi_{\underline{j}\underline{j}}$ must be treated on equal footing [4,5] otherwise divergencies can arise.

The differences between the two response functions are intrinsically related to the different gauge used to define

the coupling of the external field with the electrons. While transverse fields can be described only in terms of the transverse component of the vector potential, for longitudinal fields there are two options. One can use a scalar potential, which couples to the electron density of the system, or the longitudinal component of the vector potential, which couples to the current density. In the optical limit, i.e., in the limit where the momentum $\mathbf{q}$ carried by the external perturbation is negligible, these two gauges are called length and velocity gauge, respectively. In this limit, the distinction between longitudinal, or parallel to $\mathbf{q}$, and transverse, or perpendicular to $\mathbf{q}$, fields vanishes. However, the optical limit is also the case where many subtle differences between the two approaches arise, fundamentally because the density-based approach is ill-defined at $\mathbf{q} = 0$.

Various works in the literature have discussed and compared the two approaches either within the independent-particle (IP) picture [6–8], in which optical properties can be described in terms of a simple sum-over-states expression, or within a generalized Kohn-Sham approach [9]. These studies focus mostly on the limitations of the density-based approaches and the avoidance of divergencies in the current-based approaches. An important point of debate is whether the two approaches give the same longitudinal macroscopic dielectric function. At the linear-response level, the equivalence has been shown, but only in some specific cases, i.e., for semiconductors and insulators, for Hamiltonians with only local operators, and for absorption at resonance [10]. The comparison for metals, for Hamiltonians with nonlocal operators, and for absorption

out of resonance due to smearing,¹ has received less or no attention. More importantly, no systematic comparison of the density-based and the current-based approaches has been carried out so far at the many-body level.

The objectives of this work are (i) to better elucidate the differences between the density and the current-based approaches at the IP level and (ii) to extend the discussion to the many-body framework. In particular, at the IP level, we compare the two approaches when lifetime effects are introduced (either from first-principles or by introducing a smearing parameter). At the many-body level we consider the Bethe-Salpeter equation (BSE). Based on Green functions theory, the BSE is the fundamental equation of many-body perturbation theory for the description of linear response properties [11]. In particular, we address some important and rather subtle aspects related to the definition of the velocity operator in the current-based BSE approach [12], which did not receive proper attention so far [1,12,13].

We note that alternative approaches exist in which the explicit calculation of response functions is avoided, for example, by calculating the induced current-density in the frequency domain [4,14–16] or by calculating the time-dependent density or current-density using real-time propagation [17–19]. Many of the issues discussed in this work are also pertinent to these methods.

The manuscript is organized as follows. In Sec. II, we compare the density and the current-based approaches at a formal level, within both the independent-particle approximation and the BSE. We compare the two approaches in the optical limit $\mathbf{q} \rightarrow \mathbf{0}$ and elucidate the origin of their fundamental difference at $\mathbf{q} = \mathbf{0}$. In Sec. III, we show how an incorrect implementation of smearing and an erroneous definition of the velocity operator can lead to different spectra in the two approaches. We then show how these problems can be solved. For sake of completeness, in Sec. IV, we briefly discuss alternative approaches to calculate optical spectra. Finally, in Sec. V, we draw our conclusions.

II. FORMAL EQUIVALENCE OF DENSITY AND CURRENT-BASED APPROACHES

In this section, we review the basic equations which describe optical properties within both a density-based and a current-based approach and we compare these approaches in the optical limit $\mathbf{q} \rightarrow \mathbf{0}$. We first consider the case of noninteracting electron-hole pairs referred to in the following as IP level,² and then the case in which the electron-hole interaction is treated within the BSE of many-body perturbation theory. In both cases, we demonstrate that the two approaches should lead to the same results for the longitudinal macroscopic dielectric function (see Appendix B for its definition).

¹The differences out of resonance can be of small importance in the linear regime but they become crucial for any nonlinear phenomena because they play an important role in the construction of high-order response functions.

²In condensed matter, the IP approximations is often called RPA to be distinguished from RPA plus local field effects.

A. Noninteracting electron-hole pairs

Let us consider a collection of electrons moving in a periodic potential $v_0(\mathbf{x}) = v_0(\mathbf{r})$, with $\mathbf{x} = \mathbf{r} + \mathbf{R}$ and $\mathbf{r}$ inside the unit cell volume V , whose position is identified by the Bravais lattice vector $\mathbf{R}$. We are interested in the response of the system to a macroscopic time-dependent electromagnetic field characterized by a set of scalar and vector potentials, $\{\delta\phi(\mathbf{x},t), \delta\mathbf{A}(\mathbf{x},t)\}$. A macroscopic quantity is defined as an average taken over the unit cell whose location is given by $\mathbf{R}$ [20] (see Appendix A).

The motion of the system is then governed by the following one-particle Hamiltonian,

$$\hat{h}(t) = \left\{ \frac{1}{2} [-i\nabla_{\mathbf{x}} + \frac{1}{c}\mathbf{A}(\mathbf{x},t)]^2 + v(\mathbf{x},t) \right\} \quad (1)$$

where $\mathbf{x} = \mathbf{r} + \mathbf{R}$, and

$$v(\mathbf{x},t) = v_0(\mathbf{r}) + \delta\phi(\mathbf{R},t), \quad (2a)$$

$$\mathbf{A}(\mathbf{x},t) = \delta\mathbf{A}(\mathbf{R},t), \quad (2b)$$

for which the macroscopic external perturbations $\delta\phi(\mathbf{R},t)$ and $\delta\mathbf{A}(\mathbf{R},t)$ vanish identically for $t \leq 0$. The $v_0(\mathbf{r})$ term instead describes a periodic potential (i.e., it does not depend on $\mathbf{R}$) and can be seen as the mean field felt by the electrons. Here and throughout the paper, we use atomic units ($\hbar = m_e = e = 4\pi\epsilon_0 = 1$) with the gaussian convention for electromagnetism. It is important to notice that the perturbing potentials $\delta\phi$ and $\delta\mathbf{A}$ are external potentials and they do not take into account the contributions due to the response of the system.

The density and the current-density of the system are defined in terms of the Bloch wave functions $\psi_n(\mathbf{x},t)$, which are eigenstates of the one-particle hamiltonian $\hat{h}(t)$, as

$$\rho(\mathbf{x},t) = \sum_n f_n \psi_n^*(\mathbf{x},t) \hat{\rho} \psi_n(\mathbf{x},t), \quad (3a)$$

$$\mathbf{j}(\mathbf{x},t) = \sum_n f_n \psi_n^*(\mathbf{x},t) \hat{\mathbf{v}}(t) \psi_n(\mathbf{x},t). \quad (3b)$$

Here, $n = \{\tilde{n}\mathbf{k}\}$ is a generalized index that comprises the band index $\tilde{n}$ and the wave vector $\mathbf{k}$, and f_n are the occupations factors. In the collinear case, $\tilde{n} = \{i\sigma\}$ can be further specified as the band with the corresponding spin index σ , while in the spinorial case it is the spinorial band index. The density operator is the identity in real space $\hat{\rho} = \hat{1}$. The current-density is given in terms of the velocity operator [21]:

$$\hat{\mathbf{v}}(t) \equiv -i[\hat{h}_+(t), \mathbf{x}] - i\{\hat{h}_-(t), \mathbf{x}\}, \quad (4)$$

where $\hat{h}_{\pm} = (\hat{h} \pm \hat{h}^\dagger)/2$, $[\hat{a}, \hat{b}]$ is the commutator, while $\{\hat{a}, \hat{b}\}$ is the anticommutator. With the Hermitian Hamiltonian defined in Eq. (1) $\hat{\mathbf{v}}(t) = (-i\nabla_{\mathbf{x}} + \mathbf{A}(\mathbf{x},t)/c)$. The momentum operator $-i\nabla_{\mathbf{x}}$ gives the paramagnetic current density, i.e., $\hat{j}^p = -i\nabla_{\mathbf{x}}$, and the potential-dependent term gives the diamagnetic current density. We note that the velocity operator, and therefore the current operator, depends on the Hamiltonian. We will discuss this important point later in the paper. Density and current-density variations are induced as a response to the perturbing potentials in Eqs. (2a) and (2b).

We restrict ourselves to macroscopic longitudinal perturbations with a small transferred momentum $\mathbf{q}$. In the following, therefore, we consider the longitudinal, i.e., parallel to $\mathbf{q}$, component only of the vector potential and the current (see Appendix B). Longitudinal perturbations can be described by a scalar potential ϕ , for example in the Coulomb gauge $\nabla \cdot \mathbf{A} = 0$, or by a longitudinal vector potential $\mathbf{A}$, for example, in the (incomplete) Weyl gauge $\delta\phi = 0$. In the optical limit, the two gauges generate the so-called length and velocity gauges (see Appendix C).

The macroscopic density-density, and the longitudinal current-current response functions, $\chi_{\rho\rho}$ and χ_{jj} , respectively, can be written in reciprocal space as (see Appendix D)

$$\chi_{\rho\rho}(\mathbf{q}, \omega) \equiv \frac{\delta\rho(\mathbf{q}, \omega)}{\delta\phi(\mathbf{q}, \omega)}, \quad (5a)$$

$$\chi_{jj}(\mathbf{q}, \omega) \equiv c \frac{\delta j(\mathbf{q}, \omega)}{\delta A(\mathbf{q}, \omega)}. \quad (5b)$$

When the induced density and current density are calculated from the Hamiltonian in (1), then the response functions in Eqs. (5) are the independent particle ones, $\chi_{\rho\rho}^{\text{IP}}$ and χ_{jj}^{IP} . We can now define the longitudinal component of the macroscopic dielectric tensor $\varepsilon(\mathbf{q}; \omega)$, which conveniently describes the optical properties of semiconductors in the long wavelength limit. It can be obtained, for $\omega \neq 0$, in terms of the longitudinal current-current response function as [1]

$$\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = 1 - \frac{4\pi}{\omega^2} \chi_{jj}^{\text{IP}}(\mathbf{q}, \omega). \quad (6)$$

For $\mathbf{q} \neq \mathbf{0}$, the dielectric function can also be expressed in terms of the density-density response function as

$$\varepsilon[\chi_{\rho\rho}^{\text{IP}}](\mathbf{q}, \omega) = 1 - \frac{4\pi}{q^2} \chi_{\rho\rho}^{\text{IP}}(\mathbf{q}, \omega), \quad (7)$$

with $q = |\mathbf{q}|$. Equation (7), in the limit $\mathbf{q} \rightarrow \mathbf{0}$, is the expression commonly used for the calculations of optical properties in solids. For both expressions (6) and (7), the nonanalytic point $(\mathbf{q}, \omega) = (\mathbf{0}, 0)$ can be described only via a limiting procedure and the final result depends on the direction of the limit.

Both $\varepsilon[\chi_{jj}]$ and $\varepsilon[\chi_{\rho\rho}]$ should lead to the same result. Indeed, the two response functions are related by the expression [10,22]

$$q^2 \chi_{jj}(\mathbf{q}, \omega) = \omega^2 \chi_{\rho\rho}(\mathbf{q}, \omega), \quad (8)$$

which follows from the continuity equation $\mathbf{q} \cdot \mathbf{j} = \omega\rho$, which guarantees local charge conservation. Thus at $\mathbf{q} \neq \mathbf{0}$ and $\omega \neq 0$ relation (8) ensures $\varepsilon[\chi_{jj}] = \varepsilon[\chi_{\rho\rho}]$. We note that although we have established formal equivalence this does not guarantee numerical equivalence, as we show in Sec. III.

1. Choice of the reference one-particle hamiltonian

Within the IP picture defined by the Hamiltonian in Eq. (1) the response functions can be written as

$$\chi_{aa}^{\text{IP}}(\mathbf{q}, \omega) = -\frac{1}{V} \sum_{nm} \frac{a_{\mathbf{q},(nm)}^{\text{IP}} \tilde{a}_{\mathbf{q},(mn)}^{\text{IP}}}{\omega^+ - \Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q})} \quad (9)$$

with

$$\Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q}) = \epsilon_{\tilde{m}\mathbf{k}+\mathbf{q}}^{\text{IP}} - \epsilon_{\tilde{n}\mathbf{k}}^{\text{IP}}, \quad (10)$$

$$\Delta f_{mn}(\mathbf{q}) = f_{\tilde{m}\mathbf{k}+\mathbf{q}} - f_{\tilde{n}\mathbf{k}}, \quad (11)$$

$$a_{\mathbf{q},(nm)}^{\text{IP}} = \langle \tilde{n}\mathbf{k} | e^{-i\mathbf{q}\cdot\mathbf{r}} \hat{a} | \tilde{m}\mathbf{k} + \mathbf{q} \rangle \sqrt{\Delta f_{mn}(\mathbf{q})}, \quad (12)$$

$$\tilde{a}_{\mathbf{q},(mn)}^{\text{IP}} = \langle \tilde{m}\mathbf{k} + \mathbf{q} | e^{i\mathbf{q}\cdot\mathbf{r}} \hat{a} | \tilde{n}\mathbf{k} \rangle \sqrt{\Delta f_{mn}(\mathbf{q})} \quad (13)$$

($\tilde{m}$ and $\tilde{n}$ are the band indices, see definition after Eq. (3b); the spin index in n and m is identical in the collinear case) and

$$\omega^+ = \lim_{\eta \rightarrow 0} (\omega + i\eta), \quad (14)$$

where it is understood that the limit $\eta \rightarrow 0$ is taken at the end of the calculation. Here, $\hat{a}$ is either the one-particle density operator $\hat{\rho}$ or the paramagnetic current-density operator $\hat{j}^p$, and $|n\rangle$ are Bloch states, which are eigenstates of the equilibrium one-particle Hamiltonian $\hat{h}(t=0)$, with corresponding energies ϵ_n^{IP} and occupation numbers $0 \leq f_n \leq 1$.³ It is important to notice that the transitions with $\Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q}) = 0$ give no contribution since at equilibrium $\Delta f_{mn}(\mathbf{q}) = 0$. Thus all the summations in the present manuscript are intended without the zero-energy poles. The full current-current response function is obtained via

$$\chi_{jj}^{\text{IP}}(\mathbf{q}, \omega) = \chi_{j^p j^p}^{\text{IP}}(\mathbf{q}, \omega) + \frac{N}{V}. \quad (15)$$

We shall now choose the stationary part of the one-particle Hamiltonian (1). A common choice is the Kohn-Sham Hamiltonian from density functional theory (DFT) where

$$v_0(\mathbf{r}) = v_N(\mathbf{r}) + v_H(\mathbf{r}) + v_{xc}(\mathbf{r}), \quad (16)$$

is the equilibrium Kohn-Sham (KS) potential. It is the sum of the potential generated by the nuclei, $v_N(\mathbf{r})$, the Hartree potential, $v_H(\mathbf{r})$, and the exchange-correlation potential, $v_{xc}(\mathbf{r})$. We refer to the IP response function derived from the KS hamiltonian as χ_{aa}^{KS} . However, usually DFT-KS band structures are not a good starting point for response calculations, since, for example, the fundamental band gap is systematically underestimated in semiconductors and insulators. To improve over DFT, one can introduce a more general nonlocal and frequency dependent quasiparticle (QP) potential

$$v_{0,\sigma\sigma'}(\mathbf{x}, \mathbf{x}', \omega) = v_N(\mathbf{r}) + v_H(\mathbf{r}) + \Sigma_{xc,\sigma\sigma'}(\mathbf{x}, \mathbf{x}', \omega), \quad (17)$$

where Σ_{xc} is the exchange-correlation many-body self-energy, defined within the formalism of many-body perturbation theory (MBPT), evaluated at equilibrium. In particular we consider the (first-order) QP hamiltonian H^{QP} defined as the first-order correction in the perturbation $\Sigma_{xc} - v_{xc}$ of the KS Hamiltonian:

$$H_{nm}^{\text{QP}}(\omega) = \delta_{n,m} [\epsilon_n^{\text{KS}} + \langle n | \Sigma_{xc}(\omega) - v_{xc} | n \rangle]. \quad (18)$$

³The inclusion of $\sqrt{\Delta f_{mn}(\mathbf{q})}$ in the definition of the matrix elements of Eq. (13) allows to define in the following sections (where the case of interacting electron-hole pairs is considered) an excitonic matrix which remains Hermitian also in the general case of fractional occupation numbers. See also Ref. [58].

We have here emphasized the ω dependence of Σ_{xc} , and dropped the $\mathbf{r}$ space and σ spin dependence of both Σ_{xc} and v_{xc} . The QP eigenvalues are thus corrected KS energies

$$\epsilon_n^{\text{QP}} = \epsilon_n^{\text{KS}} + \langle n | \Sigma_{xc}(\epsilon_n^{\text{QP}}) - v_{xc} | n \rangle, \quad (19)$$

while we keep the same wave functions $\psi_n^{\text{QP}} = \psi_n^{\text{KS}}$. From the quasiparticle energies ϵ_n^{QP} , solution of Eq. (19), we can define the QP response function, χ_{aa}^{QP} , which differs from the KS response function by the replacement $\epsilon_n^{\text{KS}} \rightarrow \epsilon_n^{\text{QP}}$.

2. Expansion of the current-based approach at finite momentum

We now focus on the relation between the density-based and current-based formalism by extending the approach of Ref. [6] to $\mathbf{q} \neq \mathbf{0}$. To simplify the notation, we rewrite the response function (9) as

$$\chi_{aa}^{\text{IP}}(\mathbf{q}, \omega) = - \sum_{nm} \frac{K_{nm,\mathbf{q}}^{aa}}{\omega^+ - \Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q})}, \quad (20)$$

where $K_{nm,\mathbf{q}}^{aa} = a_{\mathbf{q},(nm)}^{\text{IP}} \tilde{a}_{\mathbf{q},(mn)}^{\text{IP}} / V$. By using the exact relation⁴

$$F(\omega) = \frac{1}{\omega - \Delta\epsilon} = -\frac{1}{\Delta\epsilon} - \frac{\omega}{\Delta\epsilon^2} + \frac{\omega^2}{(\omega - \Delta\epsilon)\Delta\epsilon^2}, \quad (21)$$

in Eq. (20) and inserting the result into Eq. (6), we can decompose $\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega)$ as

$$\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = 1 + \frac{A^{\text{IP}}(\mathbf{q})}{\omega^2} + \frac{B^{\text{IP}}(\mathbf{q})}{\omega} + C^{\text{IP}}(\mathbf{q}, \omega), \quad (22)$$

with

$$A^{\text{IP}}(\mathbf{q}) = -4\pi \left[\sum_{nm} \frac{K_{nm,\mathbf{q}}^{jp,jp}}{\Delta\epsilon_{nm}(\mathbf{q})} + \frac{N}{V} \right] = -4\pi \chi_{jj}^{\text{IP}}(\mathbf{q}, 0), \quad (23a)$$

$$B^{\text{IP}}(\mathbf{q}) = -4\pi \sum_{nm} \frac{K_{nm,\mathbf{q}}^{jp,jp}}{\Delta\epsilon_{nm}^2(\mathbf{q})}, \quad (23b)$$

$$C^{\text{IP}}(\mathbf{q}, \omega) = 4\pi \sum_{nm} \frac{K_{nm,\mathbf{q}}^{jp,jp}}{\Delta\epsilon_{nm}^2(\mathbf{q})(\omega - \Delta\epsilon_{nm}(\mathbf{q}))}, \quad (23c)$$

where in Eq. (23a), we used Eqs. (15) and (20). From the conductivity sum rule (CSR) for χ_{jj}^{IP} , given by

$$\chi_{jj}^{\text{IP}}(\mathbf{q}, 0) = \chi_{jj^p,j^p}^{\text{IP}}(\mathbf{q}, 0) + \frac{N}{V} = 0, \quad (24)$$

we see that $A^{\text{IP}}(\mathbf{q}) = 0$. Moreover, if time-reversal symmetry holds, also $B^{\text{IP}}(\mathbf{q}) = 0$. Therefore, in case of time-reversal symmetry, only the $C(\mathbf{q}, \omega)$ term survives and we have, at finite momentum, the general result

$$\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = 1 + C^{\text{IP}}(\mathbf{q}, \omega) = \varepsilon[\chi_{\rho\rho}^{\text{IP}}](\mathbf{q}, \omega). \quad (25)$$

Note that Eqs. (24) and (25) hold for $\mathbf{q} \neq \mathbf{0}$. The new definition of $\varepsilon[\chi_{jj}^{\text{IP}}]$ extends Eq. (6) to $\omega = 0$ in an analytical way. Since

⁴It can be obtained by Taylor expanding $F(\omega)$ around $\omega = 0$ up to the first order. The last term on the right-hand side is then defined from the difference $F(\omega) - F(0) - F'(0)\omega$.

Eq. (7) also holds for $\omega = 0$, the identity $\varepsilon[\chi_{jj}^{\text{IP}}] = \varepsilon[\chi_{\rho\rho}^{\text{IP}}]$ is also extended, giving the last equality⁵ in Eq. (25). In the next section, we will use (23a)–(23c) to discuss the optical limit.

3. The optical limit

We are interested in computing optical properties, for which $\omega = cq$, with ω in the order of a few eV. Therefore we consider $q \approx 0$ compared to the size of the Brillouin zone. However, $\varepsilon[\chi_{\rho\rho}^{\text{IP}}]$, given in Eq. (7), is not defined for $q = 0$ because of the $1/q^2$ term. Therefore, to obtain an explicit expression for $\varepsilon[\chi_{\rho\rho}^{\text{IP}}]$ for small q , we Taylor expand $\rho_{\mathbf{q},(nm)}^{\text{IP}}$, defined in Eq. (13), around $q = 0$,

$$\rho_{\mathbf{q},(nm)}^{\text{IP}} = -i q d_{\mathbf{q},(nm)}^{\text{IP}} + O(q^2), \quad (26)$$

where⁶ $d_{\mathbf{q},(nm)}^{\text{IP}} = \langle n | \hat{\mathbf{q}} \cdot \mathbf{x} | m \rangle \sqrt{\Delta f_{nm}(\mathbf{q})}$ with $\hat{\mathbf{q}} = \mathbf{q}/q$ the direction of $\mathbf{q}$. Substitution into Eq. (20) leads to $\chi_{\rho\rho}^{\text{IP}}(\mathbf{q}, \omega) = q^2 \chi_{dd}^{\text{IP}}(\mathbf{q}, \omega) + O(q^3)$ with

$$\chi_{dd}^{\text{IP}}(\mathbf{q}, \omega) = - \sum_{nm} \frac{K_{nm,\mathbf{q}}^{dd}}{\omega^+ - \Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q})} \quad (27)$$

the longitudinal dipole-dipole response function. Thus, for small q , we can rewrite Eq. (7) as

$$\varepsilon[\chi_{dd}^{\text{IP}}](\mathbf{q}, \omega) = 1 - 4\pi \sum_{nm} \frac{K_{nm,\mathbf{q}}^{dd}}{\omega^+ - \Delta\epsilon_{mn}^{\text{IP}}(\mathbf{q})}, \quad (28)$$

which is well defined at $\mathbf{q} = \mathbf{0}$.⁷ It is Eq. (28) that is usually implemented to compute absorption spectra of cold semiconductors and insulators in the density-based approach.

However, Eq. (28) is formally exact only in the limit $\mathbf{q} \rightarrow \mathbf{0}$, since at $\mathbf{q} = \mathbf{0}$ contributions from intraband transitions, i.e., transitions within a single band, are excluded.⁸ Instead, no such problem exists for the current-based approach. We can summarize this difference between the two approaches as

$$\lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = \varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{0}, \omega), \quad (29a)$$

$$\lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon[\chi_{dd}^{\text{IP}}](\mathbf{q}, \omega) \neq \varepsilon[\chi_{dd}^{\text{IP}}](\mathbf{0}, \omega). \quad (29b)$$

We now discuss the cases $\mathbf{q} = \mathbf{0}$ and $\mathbf{q} \rightarrow \mathbf{0}$ in more detail by separating $A^{\text{IP}}(\mathbf{q})$, $B^{\text{IP}}(\mathbf{q})$ and $C^{\text{IP}}(\mathbf{q}, \omega)$ into inter- and intraband contributions. Moreover, $A^{\text{IP}}(\mathbf{q})$ also contains the constant diamagnetic term $A^d = -4\pi N/V$.

The $\mathbf{q} = \mathbf{0}$ case: interband transitions. At $\mathbf{q} = \mathbf{0}$, only interband transitions, i.e., transitions between two different bands, contribute to the summations in Eqs. (23a)–(23c), since

⁵Equation (25) implies $q^2 K_{nm,\mathbf{q}}^{jp,jp} = \Delta\epsilon_{nm}^2(\mathbf{q}) K_{nm,\mathbf{q}}^{\rho\rho}$, which is similar, but not the same, to Eq. (8). Notice the non trivial replacement of $\omega^2 \rightarrow \Delta\epsilon_{nm}^2(\mathbf{q})$.

⁶The position operator is ill-defined when periodic boundary conditions (PBC) are imposed. Here we implicitly work in the crystal momentum representation in which the matrix elements of the position operator are redefined consistently with the PBC [59,60].

⁷Here, $d_{\mathbf{q}}$ at $\mathbf{q} = \mathbf{0}$ is the longitudinal dipole, defined by the direction of the $\mathbf{q} \rightarrow \mathbf{0}$. See also Appendix B.

⁸For finite $\mathbf{q}$, Eq. (28) is exact to first order in $\mathbf{q}$.

for intraband transitions $\Delta f_{nn} = 0$. Because of the missing intraband contributions in χ_{jj}^{IP} the CSR in Eq. (24) in general does not hold at $\mathbf{q} = \mathbf{0}$. Let us define

$$A^{\text{IP,inter}} \equiv A^{\text{IP}}(\mathbf{0}) - A^d, \quad (30a)$$

$$B^{\text{IP,inter}} \equiv B^{\text{IP}}(\mathbf{0}), \quad (30b)$$

$$C^{\text{IP,inter}}(\omega) \equiv C^{\text{IP}}(\mathbf{0}, \omega). \quad (30c)$$

One can verify⁹ that $B^{\text{IP}}(\mathbf{0}) = 0$ by exchanging n and m in Eq. (23b).

Let us first consider systems with a gap. Then $A^{\text{IP,inter}} + A^d = 0$ since the dielectric function must go to a constant [6] as $\omega \rightarrow 0$. We can thus focus on $C^{\text{IP,inter}}(\omega)$. Using Eq. (12) for the paramagnetic current-density, we can write

$$\begin{aligned} j_{\mathbf{0},(nm)}^{p,\text{IP}} &= \langle n | \hat{\mathbf{v}} | m \rangle \sqrt{\Delta f_{nm}(\mathbf{0})} \\ &= -i \langle n | \hat{\mathbf{x}} | m \rangle \Delta \epsilon_{nm}(\mathbf{0}) \sqrt{\Delta f_{nm}(\mathbf{0})} \\ &= -i d_{\mathbf{0},(nm)}^{\text{IP}} \Delta \epsilon_{nm}(\mathbf{0}), \end{aligned} \quad (31)$$

where we used $\hat{\mathbf{v}} = -i[\hat{h}, \hat{\mathbf{x}}]$ and $d_{\mathbf{0},(nm)}^{\text{IP}}$ given by Eq. (12) with $\hat{a} = \hat{\mathbf{x}}$. From this relation, we deduce that

$$K_{nm,\mathbf{0}}^{dd} = \frac{K_{nm,\mathbf{0}}^{j^p j^p}}{\Delta \epsilon_{nm}^2(\mathbf{0})}. \quad (32)$$

Substitution of this identity into Eq. (28) shows that at $\mathbf{q} = \mathbf{0}$ both $\varepsilon[\chi_{jj}^{\text{IP}}]$ and $\varepsilon[\chi_{dd}^{\text{IP}}]$ can be expressed in terms of $C^{\text{IP,inter}}$ for systems with a gap:

$$\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{0}, \omega) = \varepsilon[\chi_{dd}^{\text{IP}}](\mathbf{0}, \omega) = 1 + C^{\text{IP,inter}}(\omega). \quad (33)$$

Equation (33) proves the equivalence between the density-based and the current-based approaches for cold semiconductors and insulators.

For metals, however, we also need to describe the divergent Drude-like term. Since the current-based approach is exact also at $\mathbf{q} = \mathbf{0}$, this term must be described by $(A^{\text{IP,inter}} + A^d)/\omega^2$, i.e., the Drude tail originates from the breaking of the CSR. Thus we have

$$\varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{0}, \omega) = 1 + \frac{A^{\text{IP,inter}} + A^d}{\omega^2} + C^{\text{IP,inter}}(\omega). \quad (34)$$

Instead, the density-based approach does not contain any extra term beyond $C^{\text{IP,inter}}(\omega)$ and thus cannot describe metals at $\mathbf{q} = \mathbf{0}$. The Drude-like tails in the density-based approach can be obtained only explicitly dealing with the $\mathbf{q} \rightarrow \mathbf{0}$ limit as explained in the next section.

The $\mathbf{q} \rightarrow \mathbf{0}$ limit: intraband transitions. In the $\mathbf{q} \rightarrow \mathbf{0}$ limit, also intraband transitions contribute to the summations in Eqs. (23a)–(23c). One can thus define

$$A^{\text{IP,intra}} = \lim_{\mathbf{q} \rightarrow \mathbf{0}} A^{\text{IP}}(\mathbf{q}) - A^{\text{IP}}(\mathbf{0}) = -A^{\text{IP}}(\mathbf{0}), \quad (35a)$$

$$B^{\text{IP,intra}} = \lim_{\mathbf{q} \rightarrow \mathbf{0}} B^{\text{IP}}(\mathbf{q}) - B^{\text{IP}}(\mathbf{0}) = \lim_{\mathbf{q} \rightarrow \mathbf{0}} B^{\text{IP}}(\mathbf{q}), \quad (35b)$$

$$C^{\text{IP,intra}}(\omega) = \lim_{\mathbf{q} \rightarrow \mathbf{0}} C^{\text{IP}}(\mathbf{q}, \omega) - C^{\text{IP}}(\mathbf{0}, \omega), \quad (35c)$$

⁹Here, $B^{\text{IP,inter}} = 0$ because we are considering the longitudinal term only. Indeed, the mixed longitudinal-transverse terms can instead be different from zero and describe the anomalous Hall effect [8].

where we used Eq. (30b) and the fact that $A^{\text{IP}}(\mathbf{q} \neq \mathbf{0}) = \mathbf{0}$ owing to the CSR in Eq. (24). If time-reversal symmetry holds $B^{\text{IP}}(\mathbf{q}) = 0$ and hence $B^{\text{IP,intra}} = 0$. We note that here and in the rest of the paper, the $\mathbf{q} \rightarrow 0$ limit is taken at finite ω . Using the results of Eqs. (35a)–(35c) in Eq. (22), we obtain

$$\lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = 1 + C^{\text{IP,intra}}(\omega) + C^{\text{IP,inter}}(\omega), \quad (36)$$

where we used Eq. (30c). Owing to Eq. (29a), we can compare this result to Eq. (34) and conclude that

$$C^{\text{IP,intra}}(\omega) = \frac{A^{\text{IP,inter}} + A^d}{\omega^2}. \quad (37)$$

This means that, within the current-based approach, the Drude-like tail, which at $\mathbf{q} = \mathbf{0}$ is described by $(A^{\text{IP,inter}} + A^d)/\omega^2$, in the limit $\mathbf{q} \rightarrow \mathbf{0}$ is described via $C^{\text{IP,intra}}(\omega)$. Indeed, the exact expression for $\varepsilon[\chi_{jj}^{\text{IP}}]$ at finite $\mathbf{q}$ in Eq. (25) only depends on $C^{\text{IP}}(\mathbf{q}, \omega)$. Thus $C^{\text{IP,intra}}(\omega)$ must describe all intraband transitions in metals when $\mathbf{q} \rightarrow \mathbf{0}$ [23].

To have an explicit expression of such intraband contribution in the density-based approach, one needs to Taylor expand the energy and occupation number differences as [14]

$$(\epsilon_{n\mathbf{k}} - \epsilon_{n\mathbf{k}+\mathbf{q}}) = -v_{n\mathbf{k}} \cdot \mathbf{q} + O(q^2), \quad (38)$$

$$(f_{n\mathbf{k}} - f_{n\mathbf{k}+\mathbf{q}}) = -q \frac{df}{d\epsilon} (\nabla_{\mathbf{k}} \epsilon_{n\mathbf{k}} \cdot \hat{\mathbf{q}}) + O(q^2), \quad (39)$$

where $v_{n\mathbf{k}} = \nabla_{\mathbf{k}} \epsilon_{n\mathbf{k}}$. At the IP level, there is no Drude tail in the absorption (see Appendix E for details). Only when introducing a smearing a Drude-like peak in the absorption appears [14,15]. Experimentally such smearing also exist, because of the interaction between electrons and thus in practice a peak is always measured.

In conclusion, the current-based approach is exact both in the limit $\mathbf{q} \rightarrow \mathbf{0}$ and at $\mathbf{q} = \mathbf{0}$. In particular, if metals are considered, the Drude-like tail is present in both cases, but it is described by different terms, namely by $C^{\text{IP,intra}}(\omega)$ in the limit $\mathbf{q} \rightarrow \mathbf{0}$ and by $(A^{\text{IP,inter}} + A^d)/\omega^2$ at $\mathbf{q} = \mathbf{0}$. Also the density-based approach is exact in the limit $\mathbf{q} \rightarrow \mathbf{0}$. This can be summarized by the following set of relations:

$$\begin{aligned} \varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{0}, \omega) &= 1 + \frac{A^{\text{IP,inter}} + A^d}{\omega^2} + C^{\text{IP,inter}}(\omega) \\ &= \lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon[\chi_{jj}^{\text{IP}}](\mathbf{q}, \omega) = 1 + C^{\text{IP,intra}}(\omega) \\ &\quad + C^{\text{IP,inter}}(\omega) \\ &= \lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon[\chi_{\rho\rho}^{\text{IP}}](\mathbf{q}, \omega), \end{aligned}$$

which finally extends the identity $\varepsilon[\chi_{jj}^{\text{IP}}] = \varepsilon[\chi_{\rho\rho}^{\text{IP}}]$ also to the $\mathbf{q} = \mathbf{0}$ case.

B. Interacting electron-hole pairs

So far, we have only considered independent particles. We now also take into account the electron-hole interaction by considering the variations induced in the Hartree and the exchange-correlation self-energy by the external potential. Within MBPT such variations can be conveniently described using the BSE [1] for the (time-ordered) two-particle propa-

gator L , which reads

$$\bar{L}(1,2,1',2') = L_0(1,2,1',2') + \int d3d4d5d6 \\ \times L_0(1,4,1',3)\bar{\Xi}(3,5,4,6)\bar{L}(6,2,5,2'), \quad (40)$$

where $i \equiv \mathbf{r}_i, t_i$. In Eq. (40), L_0 is given in terms of QP Green's functions as $L_0(1,2,1',2') = -iG^{\text{QP}}(1,2')G^{\text{QP}}(2,1')$ and the four-point kernel $\bar{\Xi}(3,5,4,6)$ is given by

$$\bar{\Xi}(3,5,4,6) = i \frac{\delta[\bar{v}_H(3)\delta(3,4) + \delta\Sigma_{xc}(3,4)]}{\delta G(6,5)}, \quad (41)$$

where $\bar{v}_H$ is the Hartree potential without the long-range component of the Coulomb potential, $v_c(\mathbf{G}=0)$. We are now looking at the self-consistent response of the system to a macroscopic field composed of both the external and the induced macroscopic field. Therefore $v_c(\mathbf{G}=0)$ is effectively removed [24]. We use the GW self-energy with an instantaneous screened Coulomb potential W . In this case, the propagator L depends only on the time difference $\tau = t_1 - t_2$ ¹⁰. A Fourier transformation to frequency space leads to

$$\bar{L}(\omega) = L_0(\omega) + L_0(\omega) \bar{\Xi} \bar{L}(\omega), \quad (42)$$

where, for notational convenience, we dropped the spin and space arguments.¹¹

The BSE can be mapped onto an effective two-particle equation, written in a basis of electron-hole transitions (nm), according to [25,26]

$$H_{(nm)(n'm')}^{\text{Exc}}(\mathbf{q}) A_{\lambda,\mathbf{q}}^{(n'm')} = E_{\lambda}(\mathbf{q}) A_{\lambda,\mathbf{q}}^{(nm)}, \quad (43)$$

where $H^{\text{Exc}}(\mathbf{q})$ is the excitonic Hamiltonian with eigenvectors $A_{\lambda,\mathbf{q}}$ and eigenvalues $E_{\lambda}(\mathbf{q})$. The (retarded)¹² particle-hole propagator $\bar{L}$ can be obtained via

$$\bar{L}_{(nm)(n'm')}(\mathbf{q},\omega) = \sum_{\lambda\lambda'} \frac{B_{\lambda,\mathbf{q}}^{(nm)} S_{\lambda\lambda',\mathbf{q}}^{-1} B_{\lambda',\mathbf{q}}^{*(n'm')}}{\omega^+ - E_{\lambda}(\mathbf{q})},$$

where $B_{\lambda,\mathbf{q}}$ and the overlap matrix $S_{\lambda\lambda',\mathbf{q}}$ are defined by

$$B_{\lambda,\mathbf{q}}^{(nm)} = A_{\lambda,\mathbf{q}}^{(nm)} \sqrt{\Delta f_{nm}(\mathbf{q})}, \quad (44)$$

$$S_{\lambda\lambda',\mathbf{q}} = \sum_{nm} A_{\lambda,\mathbf{q}}^{*(nm)} A_{\lambda',\mathbf{q}}^{(nm)}. \quad (45)$$

¹⁰As commonly done in the literature, we neglect the term $i\delta W/\delta G$ in the kernel.

¹¹For a detailed treatment of the space indexes at finite momentum see Ref. [26]; for the treatment of occupations factors, see Ref. [58].

¹²The exact Dyson equation holds only for the time-ordered two-particles propagator, which is formally derived assuming zero temperature (i.e., integer occupation numbers also in case of metals). To consider fractional occupations, one would need to introduce a finite temperature formalism. However, using a static kernel, the Dyson equation at finite temperature reduces to a Dyson equation identical to Eq. (42) but for the retarded propagator, which is indeed what is needed to define the dielectric function. Thus, from now on, we can consider all quantities as retarded functions and forget about the time-ordered formalism.

Upon solving Eq. (43), one can obtain the density-density and the current-current excitonic response functions $\bar{\chi}_{aa}^{\text{Exc}}$ as

$$\bar{\chi}_{aa}^{\text{Exc}}(\mathbf{q},\omega) = -\frac{1}{V} \sum_{\lambda\lambda'} a_{\mathbf{q},\lambda}^{\text{Exc}} \frac{S_{\lambda\lambda',\mathbf{q}}^{-1}}{\omega^+ - E_{\lambda}(\mathbf{q})} \bar{a}_{\mathbf{q},\lambda'}^{\text{Exc}}, \quad (46)$$

where $a_{\mathbf{q},\lambda}^{\text{Exc}}$ and $\bar{a}_{\mathbf{q},\lambda'}^{\text{Exc}}$ are defined analogously to $a_{\mathbf{q},\lambda}$ and $\bar{a}_{\mathbf{q},\lambda'}$ in Eqs. (12) and (13) but the expectation value is with respect to the excitonic wave function. As for the IP case, the zero-energy transitions give no contribution to the summation¹³ since $\Delta f_{nm}(\mathbf{q}) = 0$ and thus $B_{\lambda,\mathbf{q}}^{(nm)} = 0$. Note that neglecting the kernel $\bar{\Xi}$ in the BSE (42), Eq. (46) reduces to the IP response function given in Eq. (9).

Substitution of $\bar{\chi}_{jj}^{\text{Exc}}$ and $\bar{\chi}_{\rho\rho}^{\text{Exc}}$ in Eqs. (6) and (7), respectively, yields an expression for the macroscopic dielectric tensor in the current- and density-based approach. As in the IP case, the two expressions are identical for $\mathbf{q} \neq \mathbf{0}$ and $\omega \neq 0$ thanks to Eq. (8).

1. The optical limit

The analysis for the optical limit in Secs. II A 2 and II A 3 also applies to the excitonic case. In particular, by rewriting the expression for the excitonic response function as

$$\bar{\chi}_{aa}^{\text{Exc}}(\mathbf{q},\omega) = -\sum_{\lambda\lambda'} \frac{K_{\lambda\lambda',\mathbf{q}}^{aa}}{\omega^+ - E_{\lambda}(\mathbf{q})}, \quad (47)$$

where $K_{\lambda\lambda',\mathbf{q}}^{aa} = a_{\mathbf{q},\lambda} S_{\lambda\lambda',\mathbf{q}}^{-1} \bar{a}_{\mathbf{q},\lambda'}/V$, one obtains

$$A^{\text{Exc}}(\mathbf{q}) = -4\pi \left[\sum_{\lambda\lambda'} \frac{K_{\lambda\lambda',\mathbf{q}}^{j^p j^p}}{E_{\lambda}(\mathbf{q})} + \frac{N}{V} \right], \quad (48a)$$

$$B^{\text{Exc}}(\mathbf{q}) = -4\pi \sum_{\lambda\lambda'} \frac{K_{\lambda\lambda',\mathbf{q}}^{j^p j^p}}{E_{\lambda}^2(\mathbf{q})}, \quad (48b)$$

$$C^{\text{Exc}}(\mathbf{q},\omega) = 4\pi \sum_{\lambda\lambda'} \frac{K_{\lambda\lambda',\mathbf{q}}^{j^p j^p}}{E_{\lambda}^2(\mathbf{q})(\omega - E_{\lambda}(\mathbf{q}))}. \quad (48c)$$

The interband dielectric function in terms of the excitonic dipole-dipole response function χ_{dd}^{Exc} reads

$$\varepsilon[\chi_{dd}^{\text{Exc}}](\mathbf{q},\omega) = 1 + \frac{4\pi}{V} \sum_{\lambda\lambda'} \frac{K_{\lambda\lambda',\mathbf{q}}^{dd}}{\omega^+ - E_{\lambda}(\mathbf{q})}, \quad (49)$$

where now $K_{\lambda\lambda',\mathbf{q}}^{dd}$ contains the longitudinal excitonic dipoles $d_{\mathbf{q},\lambda}^{\text{Exc}} = \sum_{nm} A_{\lambda,\mathbf{q}}^{(nm)} x_{(nm)} \sqrt{\Delta f_{nm}(\mathbf{q})}$.

Finally, the analogous of the relation (32) exists also for the excitonic case:

$$\frac{K_{\lambda\lambda',\mathbf{0}}^{j^p j^p}}{E_{\lambda}^2(\mathbf{0})} = K_{\lambda\lambda',\mathbf{0}}^{dd}, \quad (50)$$

¹³We assume that zero-energy transitions at the BSE level originates from zero-energy transitions at the IP level. Zero-energy poles at the BSE level may originate from finite energies transition at the IP level as well. However, this case would point to an instability of the ground state, which would be degenerate to an excited state. We exclude this possibility in the present work.

from which expressions analogous to Eqs. (34) and (35) can be written for $\varepsilon[\chi_{jj}^{\text{Exc}}]$.

III. ISSUES IN THE PRACTICAL IMPLEMENTATION OF CURRENT-BASED APPROACHES

In the previous section, the equivalence between the current-based and density-based approaches was established for the longitudinal macroscopic dielectric function. In the present section, we compute optical absorption in a semiconductor (bulk silicon), an insulator (LiF), and a metal (copper) comparing the two approaches numerically, i.e., using both Eq. (6) for the current-based approach and Eq. (7) for the density-based approach. In doing so we will show potential pitfalls in the implementation of current-based approaches due to: (i) the use of a smearing parameter (Sec. III B); (ii) the violation of the conductivity sum rule (Sec. III C); (iii) the inclusion of lifetimes (Sec. III D); and (iv) the inclusion of QP energy corrections and excitonic effects with an incorrect velocity operator (Sec. III E). Moreover, we demonstrate how those pitfalls can be avoided.

A. Computational details

The response functions entering Eqs. (6) and (7) are constructed starting from ground state DFT calculations performed with either the QUANTUM ESPRESSO code [27] (Si and Cu) or the ABINIT code [28] (LiF) using norm conserving pseudopotentials. The ground-state of all three materials have been calculated by using the local density approximation (LDA) for the exchange-correlation functional. For Si, we used four valence electrons ($3s^2 3p^2$ configuration), a face-centered cubic (FCC) cell with a two atoms (diamond structure) and the experimental lattice parameter of 10.18 Bohr. For calculating the ground-state density we use an energy cutoff of 10 Ha and a $6 \times 6 \times 6$ sampling of the Brillouin zone (BZ). For the calculation of the response function, we used instead a $16 \times 16 \times 16$ sampling of the BZ, resulting in 145 k points in the irreducible BZ (IBZ) and 4096 in the BZ. For LiF, we used eight valence electrons ($2s^1$ configuration for Li and $2s^2 2p^5$ for F) [29], a FCC cell with two atoms (sodium-chloride structure) and the experimental lattice parameter of 7.70 Bohr. For calculating the ground state density and the response function, we use an energy cutoff of 40 Ha with a $8 \times 8 \times 8$ sampling of the BZ, resulting in 29 (512) k points in the IBZ (BZ). For Cu, we used with 11 valence electrons ($3d^{10} 4s^1$ configuration), a FCC cell with a single atom and the experimental lattice parameter of 6.82 Bohr. For calculating the ground state density and the response function, we use 32.5 Ha and a $16 \times 16 \times 16$ sampling of the BZ, resulting in 145 (4096) k points in the IBZ (BZ).

We computed the dielectric function starting from the DFT-KS wave functions and energies using the YAMBO code [30] where we implemented the equations for the current-based approach.¹⁴ For Si and LiF, we considered electron-hole pairs built from the top three valence and the bottom three conduction bands. For Cu, we included 30 bands in the

band summation. A scissor operator is used to mimic the effect of the GW quasiparticle corrections in Si (0.8 eV) and LiF (5.8 eV) consistently to what already reported in the literature. For the BSE calculations, the static screening in the random-phase approximation is computed using 50 bands in the band summation and 2.3 Ha energy cutoff in the summation over reciprocal lattice vectors for Si, and 30 bands and a 3.6 Ha energy cutoff for LiF.

We also consider QP lifetimes by introducing an imaginary part in the QP energies. To mimic the effect of the electron-phonon Fan self-energy [31,32], we use a term proportional to the density of states. To mimic the effect of the GW self-energy [33], we use a term, which grows quadratically in energy, from the Fermi level in Cu and from the conduction band maximum (valence band minimum) plus (minus) the band gap in Si.

B. Smearing parameter and conductivity sum rule

The macroscopic density-density and paramagnetic current-current response functions in Eq. (9) contain the infinitesimal η , which ensures causality and avoids having poles on the real axis. Numerically, η can be used as a smearing parameter to simulate finite lifetime effects of the excitations. As a result, each peak in the absorption spectrum acquires a finite width. This is done by replacing

$$\omega^+ = \lim_{\eta \rightarrow 0} (\omega + i\eta) \rightarrow z = \omega + i\eta \quad (51)$$

in Eq. (9) for both the density-based and the current-based approach, where η is now a finite number. In the current-based approach, however, the frequency ω enters also in the definition of the dielectric function, Eq. (6), as a factor $1/\omega^2$. Moreover, it is common to numerically impose [5,16] the CSR [Eq. (24)] replacing the diamagnetic term, N/V , with minus the paramagnetic term, $-\chi_{jp,jp}^{\text{IP}}(\omega)$, evaluated at $\omega = 0$. It is thus natural to wonder whether we should replace also $1/\omega^2$ by $1/z^2$ and if we should use $-\chi_{jp,jp}^{\text{IP}}(z)$ evaluated at $\omega = 0$ or $z = 0$ while imposing the CSR.

In Fig. 1, we plot the optical spectra ($\mathbf{q} = 0$) obtained for LiF and Si inserting $\chi_{\rho\rho}^{\text{IP}}(z)$ in Eq. (7) and $\chi_{jp,jp}^{\text{IP}}(z)$ in Eq. (6). For the current-based approach we consider both the factors $1/\omega^2$ and $1/z^2$ in the definition of the dielectric function [Eq. (6)]. In both cases, the diamagnetic term is replaced by $-\chi_{jp,jp}^{\text{IP}}(i\eta)$, i.e., the CSR is imposed with $\omega = 0$. The optical spectra obtained within the current-based approach are different from those obtained within the density-based approach. In particular, they present clearly unphysical features: the case with the $1/\omega^2$ factor in Eq. (6) shows a divergent low energy contribution which resembles the Drude like behavior of metals; the case with the $1/z^2$ factor shows a negative peak at $\omega = \eta$. Both unphysical features are related to the existence of a finite smearing in the low frequency region of the spectrum.

One possible solution is to adopt the recipe proposed by Cazzaniga *et al.* [34] in another context, i.e., to choose $\tilde{z} = \sqrt{\omega^2 + 2i\eta\omega}$, instead of $z = \omega + i\eta$. The latter choice implies no smearing at $\omega = 0$ and a CSR uniquely defined by $N/V = -\chi_{jp,jp}^{\text{IP}}(0)$. For the case of Si, we show this recipe cures both unphysical features although some residual numerical noise remains.

¹⁴YAMBO standard implementation uses a density-based approach.

FIG. 1. Optical absorption in bulk LiF (a) and Si (b) at the IP level. The spectra obtained by replacing ω^+ by $\omega + i\eta$ in Eq. (9), for the density-based approach, Eq. (7), (grey shadow) and the current-based approach, Eq. (6) with either $1/\omega^2$ (red dashed line) or $1/z^2$ (blue continuous line), are compared. Results with the numerical recipe $\bar{z} = \sqrt{\omega + 2i\omega\eta}$ are also shown. Here, $\eta = 0.1$ eV for Si and $\eta = 0.2$ eV for LiF. The conductivity sum rule is always enforced as explained in the main text.

A more rigorous solution requires to consider again the expansion defined by Eq. (21). Having a smearing parameter we can now expand either around $\omega = 0$ or around $z = 0$ (i.e., $\omega = -i\eta$). The expansion around $\omega = 0$ is more suited to analyze the case with the $1/\omega^2$ factor in Eq. (6) and yields

$$\varepsilon[\chi_{jj}^{\text{IP}}](\omega) = 1 + \frac{1}{\omega^2} A_{\eta}^{\text{IP}} + \frac{1}{\omega} B_{\eta}^{\text{IP}} + C^{\text{IP}}(\omega + i\eta). \quad (52)$$

The paramagnetic term entering A_{η}^{IP} is correctly balanced by replacing $N/V \rightarrow -\chi_{jp,jp}^{\text{IP}}(i\eta)$ in the diamagnetic term. However, B_{η} is not zero anymore (it is zero only for $\eta = 0$) and thus leads to a divergence in the spectrum at $\omega = 0$.

The expansion around $z = 0$ is more suited to analyze the case with the $1/z^2$ factor in Eq. (6) and yields

$$\varepsilon[\chi_{jj}^{\text{IP}}](z) = 1 + \frac{1}{z^2} A^{\text{IP}} + \frac{1}{z} B^{\text{IP}} + C^{\text{IP}}(z). \quad (53)$$

In this case, B^{IP} is numerically zero as expected theoretically, however, the paramagnetic term entering A^{IP} is not correctly balanced [since we are using $N/V \rightarrow -\chi_{jp,jp}^{\text{IP}}(i\eta)$] and the CSR is broken. A^{IP} is here multiplied by $1/z^2$ leading to a negative energy peak around $\omega = \eta$. To summarize, in order to avoid unphysical divergencies and negative peaks, there are two options: (1) the $1/\omega^2$ factor can be used in Eq. (6) together with the CSR imposed by $N/V \rightarrow -\chi_{jp,jp}^{\text{IP}}(i\eta)$ and balancing B_{η}^{IP} by a proper counter term; (2) a $1/z^2$ term can be used in Eq. (6) together with the CSR imposed by $N/V \rightarrow -\chi_{jp,jp}^{\text{IP}}(0)$. The latter option is the most straightforward to implement and we have tested that cures the unphysical negative peak at $\omega = \eta$ and gives the same spectra as within the density-based approach.

C. The conductivity sum rule and the Drude term

The current-current response function in Eq. (15) consists of two terms, a constant diamagnetic term N/V and a paramagnetic term given by Eq. (9). In practice, the sum over states in Eq. (9) is truncated. As a consequence the CSR in Eq. (24) is no longer satisfied, and it becomes impossible to converge the optical spectra for small frequencies. To solve these problems, one can impose the CSR by replacing [4,14,15] the diamagnetic term N/V with $-\chi_{jp,jp}(\mathbf{q},0)$ (or $-\chi_{jp,jp}(\mathbf{q},i\eta)$) as we did in the previous section). Thus the diamagnetic and paramagnetic contributions are treated on equal footing and no convergence problems occur.

At $\mathbf{q} = 0$, this strategy poses no problems for systems with a gap. For metals, instead, it suppresses the Drude tail, which is described by the term A^{IP}/ω^2 on the right-hand side of Eq. (34). This occurs because the CSR in general does not hold at $\mathbf{q} = 0$ since intraband transitions are excluded in the sum over states in $\chi_{jp,jp}$. We thus consider here the case of a metal, Cu, and compute its spectrum without imposing the CSR. Since the diamagnetic term is purely real, we need to use the $1/z^2$ strategy as discussed previously. However, without imposing the CSR, calculations never converge. This is shown in Fig. 2: the Drude tail in Cu has a wrong behavior, whereas in Si, where converged calculations should give no absorption at low energy, an artificial Drude-like tail appears.

We found that the best solution is to enforce the CSR and to calculate the Drude term through the explicit inclusion of intraband transitions as described for the density-based approach. A faster convergence of the latter contribution can be obtained using the tetrahedron method for the integration in the Brillouin zone [14,38].

D. Many-body lifetimes

In Sec. III B, the finite width of the peaks was obtained by introducing an *ad hoc* smearing parameter. A more physically motivated approach is to consider finite lifetimes γ originating from the imaginary parts of the many-body self-energy. For example, it has been shown that in a semiconductor such as Si the finite width of the peaks is well-described by means of the Fan and *GW* self-energies, which account for electron-phonon [31,39] and electron-electron [33] scattering processes, respectively. To illustrate the effects of such lifetimes in the following, we will consider the contributions due to the Fan self-energy.

FIG. 2. Optical absorption in bulk Cu (a) and Si (b) at the IP level. Red dashed lines: spectra obtained in the current-based approach using Eq. (34) without enforcing the conductivity sum rule [Eq. (15)]; the various lines correspond to different number of bands. Grey shadow: spectra obtained in the density-based approach [Eq. (7)] and in the current-based approach by enforcing the conductivity sum rule [Eq. (15)]. Brown shadow: Drude term added via a Drude model (for Copper). Blue dots, red dots, and black continuous bold line: experimental data from Refs. [35,36], and [37], respectively.

We define modified KS energies $\tilde{\epsilon}_n^{\text{KS}}$ as

$$\tilde{\epsilon}_n^{\text{KS}} = \epsilon_n^{\text{KS}} + i\gamma_n, \quad (54)$$

and use them to compute the absorption both in the current-based and in the density-based approach. The KS energies $\tilde{\epsilon}_n^{\text{KS}}$ correspond to the eigenenergies of the Hamiltonian (18), in which only the imaginary part of the Fan self-energy is considered. The underlying Hamiltonian, which we will indicate as $\tilde{H}_{\text{KS}}$, is diagonal in the same basis set in which H_{KS} is diagonal, i.e., $\tilde{\psi}_n^{\text{KS}} \approx \psi_n^{\text{KS}}$ and thus $\tilde{x}_{nm}^{\text{KS}} = x_{nm}^{\text{KS}}$. The velocity matrix elements however change because the velocity operator is proportional to the hamiltonian itself. Using Eq. (4), the velocity matrix elements read

$$\begin{aligned} \tilde{v}_{nm}^{\text{KS}} &= -i \tilde{x}_{nm}^{\text{KS}} [\tilde{\epsilon}_n^{\text{KS}} - (\tilde{\epsilon}_m^{\text{KS}})^*] \\ &= v_{nm}^{\text{KS}} \frac{\tilde{\epsilon}_n^{\text{KS}} - (\tilde{\epsilon}_m^{\text{KS}})^*}{\epsilon_n^{\text{KS}} - \epsilon_m^{\text{KS}}}. \end{aligned} \quad (55)$$

FIG. 3. Optical absorption in bulk Cu (a) and Si (b) at the IP level. Red dashed line: spectra obtained in the current-based approach using the complex one-particle energies (54) in Eq. (9). Grey shadow: spectra obtained in the density-based approach [Eq. (7)] and in the current-based approach by using the complex one-particle energies (54) and the velocity operator (55) [with (56)] in Eq. (9). Brown shadow: as in Fig. 2. Blue dots, red dots, and bold continuous black line: as in Fig. 2.

Such expression generalizes the result by Del Sole *et al.* [40] (that we use in the next section) to the case of complex energies and is consistent with the findings of Tokman.¹⁵

Moreover, since $\tilde{H}_{\text{KS}}$ is non-Hermitian (although it is still a normal matrix), the velocity operator is also non-Hermitian. This means in practice

$$\tilde{v}_{nm}^{\text{KS}} \neq (\tilde{v}_{mn}^{\text{KS}})^*, \quad (56)$$

and thus the numerator of the response function [Eq. (9)] in the current-based approach cannot be written as a square modulus $|\tilde{v}_{nm}^{\text{KS}}|^2$ anymore. One may wonder if—having a non positive defined numerator—the spectrum may become negative.

¹⁵Reference [53] discusses the connection between the time derivative of the dipole operator and the velocity operator in case of a dephasing of the polarization (i.e., an imaginary term in the Hamiltonian) is considered.

In Fig. 3, we show for Cu and Si that this is not the case: the spectrum is well defined and matches the one obtained in the density-based approach as long as the non-Hermiticity of the velocity operator is correctly taken into account. If instead we ignore the non-Hermiticity of the velocity operator and use $|\tilde{v}_{nm}^{\text{KS}}|^2$ in the numerator of Eq. (9), a spurious divergence appears at low energy for Si and the Drude tail is not correctly described for Cu.

E. Quasiparticle energies and excitonic effects

We finally consider the dielectric function beyond the IP approximation by using the Bethe-Salpeter equation. We include both the GW corrections to the KS band structure and the effect of the electron-hole interaction in the absorption. As for the case of the QP lifetimes we have to consider a renormalized velocity operator [40],

$$v_{nm}^{\text{QP}} = -i x_{nm}^{\text{QP}} (\epsilon_n^{\text{QP}} - \epsilon_m^{\text{QP}}) \quad (57)$$

$$= v_{nm}^{\text{KS}} \frac{\epsilon_n^{\text{QP}} - \epsilon_m^{\text{QP}}}{\epsilon_n^{\text{KS}} - \epsilon_m^{\text{KS}}}, \quad (58)$$

which corresponds to the quasiparticle Hamiltonian [Eq. (18)] with a GW self-energy. However this is not the only correction to be considered. If the dielectric function is computed by diagonalizing the excitonic Hamiltonian given by Eq. (43), then it is expressed in terms of the excitonic dipole matrix elements x_λ^{Exc} in the density-based approach,

$$x_\lambda^{\text{Exc}} = \sum_{nm} A_{nm}^\lambda x_{nm}^{\text{QP}}, \quad (59)$$

or via the excitonic velocity matrix elements v_λ^{Exc} , in the current-based approach. One might be tempted, in analogy with Eq. (59), to define

$$v_\lambda^{\text{Exc}} = \sum_{nm} A_{nm}^\lambda v_{nm}^{\text{QP}}. \quad (60)$$

However, this expression—which has been reported in the literature [12,41–43]¹⁶—is not correct since it does not correspond to the underlying excitonic Hamiltonian H^{Exc} given by Eq. (43). The excitonic velocity hence must read

$$v_\lambda^{\text{Exc}} = -i \langle [H^{\text{Exc}}, x] \rangle = -i x_\lambda^{\text{Exc}} E_\lambda \quad (61)$$

$$= \sum_{nm} A_{nm}^\lambda v_{nm}^{\text{QP}} \frac{E_\lambda}{\epsilon_n^{\text{QP}} - \epsilon_m^{\text{QP}}}, \quad (62)$$

which in general is different from Eq. (60).

In Fig. 4, we compare the absorption spectrum in the density-based approach with the current-based approach results with and without the renormalized velocity operator, i.e., considering the corrections due to Eqs. (58) and (62). We notice that the two corrections in general partially cancel each other since $\epsilon_n^{\text{QP}} - \epsilon_m^{\text{QP}} > \epsilon_n^{\text{KS}} - \epsilon_m^{\text{KS}}$ and $E_\lambda < \epsilon_n^{\text{QP}} - \epsilon_m^{\text{QP}}$ and the resulting error in the absorption intensity is proportional

FIG. 4. Optical absorption in bulk LiF (a) and Si (b) at the BSE level. Black continuous line: spectra obtained in the current-based approach [Eq. (6)] neglecting the corrections (58) and (62). Red dashed line: spectra obtained in the current-based approach [Eq. (6)] considering only the correction (58). Blue dot-dashed line: spectra obtained in the current-based approach [Eq. (6)] considering only the correction (62). Grey shadow: spectra obtained in the density-based approach [Eq. (7)] and in the current-based approach considering the corrections (58) and (62). Black dots: experimental data are from Refs. [44,45].

to $|E_\lambda - (\epsilon_n^{\text{KS}} - \epsilon_m^{\text{KS}})| / |\epsilon_n^{\text{KS}} - \epsilon_m^{\text{KS}}|$. There is thus an error cancellation in the intensity due to the fact that the onset of the KS absorption is often not too different from the onset of the BSE absorption. The opposite sign of the two corrections is evident when they are considered independently. If only Eq. (58) is considered, the absorption spectrum intensity is strongly overestimated. Conversely the spectrum intensity is strongly underestimated if only Eq. (62) is considered. Only when including both the renormalization of the velocity due the quasiparticle corrections and the nonlocal operator we recover the results obtained within the density-based approach.

Regarding the computational cost, we note that if Eq. (62) is used to evaluate the excitonic velocity operator v_λ^{Exc} , then iterative schemes to calculate the dielectric function, such as the Lanczos-Haydock method [46–48], are precluded since v_λ^{Exc} in Eq. (62) explicitly depends on the BSE energies E_λ .

¹⁶We notice that in the last arxiv version (<https://arxiv.org/abs/1111.4429v3>) of Ref. [43], the correct definition of the excitonic velocity operator is reported; Eq. (45) in the arxiv.

Instead, one should use Eq. (61) and explicitly calculate the commutator of the dipole operator and the excitonic Hamiltonian H^{Exc} which is cumbersome since H^{Exc} contains nonlocal kernels. This issue also arises in approaches in which the QP corrections are calculated in a nonperturbative way, i.e., when a nondiagonal self-energy is considered, and thus the commutator with such a self-energy should in principle be computed [49].

IV. DIRECT CALCULATION OF THE INDUCED DENSITY, POLARIZATION AND CURRENT

For sake of completeness, we extend the discussion by considering alternative approaches in which optical response functions are not computed as sum over states [Eq. (9)], but rather using the right-hand side of Eqs. (5): the change in the density or in the current-density induced by a perturbing field [19,50,51] is computed first and the macroscopic response functions are then obtained by dividing the induced quantities by the perturbing fields.

A way to access the density and the current-density is through the one particle time-dependent density-matrix of the system $\varrho(\mathbf{x}, \mathbf{x}', t)$. The general equation of motion (EOM) for the density matrix can be written in the Von Neumann form [52]. It reads

$$\hat{L}(t) \varrho(t) - \hat{R}(t) \varrho(t) = 0, \quad (63)$$

where the Liouvillian operator $\hat{L}(t)$, defined by

$$\hat{L}(t) \varrho(t) = i \partial_t \varrho(t) - [h_+(t), \varrho(t)], \quad (64)$$

describes the coherent evolution in terms of the Hermitian part of the Hamiltonian $\hat{h}_+(t)$. The relaxation operator $\hat{R}$, defined by

$$\hat{R}(t) \varrho(t) = \{h_-(t), \varrho(t)\}, \quad (65)$$

describes relaxation processes in terms of the skew-Hermitian part of the Hamiltonian $\hat{h}_-(t)$.¹⁷ We can solve the equation for $\varrho(t)$ in the equilibrium one-particle basis set $\varrho_{nm}(t) = \langle \psi_m | \varrho(t) | \psi_n \rangle$ with the initial condition $\varrho_{nm}(t=0) = \delta_{nm} f_n$. The density and current-density can then be obtained as

$$\rho(\mathbf{x}, t) = \sum_{nm} \varrho_{nm}(t) \psi_n^*(\mathbf{x}) \hat{\rho} \psi_m(\mathbf{x}), \quad (66a)$$

$$\mathbf{j}(\mathbf{x}, t) = \sum_{nm} \varrho_{nm}(t) \psi_n^*(\mathbf{x}) \hat{\mathbf{v}}(t) \psi_m(\mathbf{x}). \quad (66b)$$

If the Hamiltonian is expressed in terms of quasiparticle energies and only the variation of the static screened exchange self-energy is considered, this approach has been proven [17], to linear order, to be equivalent to the BSE. In this case the use of a smearing parameter η in the BSE corresponds to setting the non-Hermitian part of the Hamiltonian proportional to η .

Since the Hamiltonian is gauge dependent, so is the EOM in Eq. (63) and its solution $\varrho(t)$. Using the gauge function $\Lambda(\mathbf{x}, t)$

defined in Appendix C, which transforms the potentials from one gauge to another, $\hat{L}(t)$, $\hat{R}(t)$, and $\varrho(t)$ transform according to

$$\hat{L}_2 = e^{i\chi} \hat{L}_1 e^{-i\chi}, \quad (67)$$

$$\hat{R}_2 = e^{i\chi} \hat{R}_1 e^{-i\chi}, \quad (68)$$

$$\varrho_2 = \varrho_1 e^{i\chi}, \quad (69)$$

where $\chi = c [\Lambda(\mathbf{x}, t) - \Lambda(\mathbf{x}', t)]$. One can show that a gauge transformation preserves the current, the density, the polarization and the electromagnetic energy [53] only if all quantities are gauge transformed together. We note that in the velocity gauge the relaxation operator acquires a dependence on the perturbing potential, not present in the length gauge [7,53]. At finite momentum Eqs. (67)–(69) are all is needed to prove the equivalence between the density- and current-based approaches for the description of optical properties, similarly to Eq. (8) for the response functions. Propagating the density-matrix in the length gauge [with potential $\phi(t)$] and then computing the density variation the macroscopic density-density response function is obtained. Propagating the density-matrix in the velocity gauge [with potential $\mathbf{A}(t)$] and then computing the current-density variation the macroscopic current-current response function is obtained.

Again difficulties arise if one considers the optical limit $\mathbf{q} \rightarrow \mathbf{0}$. Indeed, at $\mathbf{q} = \mathbf{0}$ the length gauge cannot be formulated in terms of the coupling with the density only [54,55]. The induced macroscopic polarization needs to be defined. Up to first order in the perturbing field, it can be constructed¹⁸ from the density matrix as

$$P(t) = \sum_{n \neq m} \varrho_{nm}(t) x_{0,nm}. \quad (70)$$

The longitudinal¹⁹ dipole-dipole response function can then be defined as $\chi_{dd}(\omega) = \delta P(\omega) / \delta E(\omega)$, where E is the total macroscopic electric field. Thanks to Eq. (70) it is possible to show the formal equivalence [53] between the two formalisms also at $\mathbf{q} = \mathbf{0}$ for cold semiconductors. As previously, $\chi_{dd}(\omega)$ describes, however, only the interband and not the intraband contribution. The latter can be obtained, in the length gauge, only by explicitly considering the $\mathbf{q} \rightarrow \mathbf{0}$ limit. The direct numerical calculation of $\delta \rho(\mathbf{q}, \omega)$ at very small $\mathbf{q}$ is however not feasible, and one would need to analytically deal with the small $\mathbf{q}$ dependence as we do in Appendix E for the response function. Instead, the current-based formalism can be directly formulated also at $\mathbf{q} = \mathbf{0}$ and the intraband contribution is also included. However, similar to what discussed previously, one must be careful because of potential breaking of the CSR [Eq. (24)].

¹⁸For a discussion and a general expression, valid at all orders, see Ref. [63].

¹⁹While the density-density response function can be used only to compute the longitudinal response, the dipole-dipole response function, like the current-current one, can also describe transverse and mixed (longitudinal-transverse) terms.

¹⁷This EOM can also be derived as an approximation to the nonequilibrium Green's function theory or quantum kinetic theory [61,62] where the density matrix is the time diagonal of the lesser Green function $\varrho(t) = -i G^<(t, t)$.

V. CONCLUSIONS

We compared the optical absorption of extended systems calculated from the density-density and current-current linear response functions obtained within many-body perturbation theory. We did this by studying the longitudinal macroscopic dielectric function both on a formal and on a numerical level.

We showed that for a finite momentum $\mathbf{q}$, carried by the external perturbation, the two approaches are formally equivalent thanks to the continuity equation, which relates the density to the longitudinal current. For the case of vanishing momentum, $\mathbf{q} = \mathbf{0}$, the optical absorption is not well defined in terms of the density-density response function. A small $\mathbf{q}$ expansion is needed, which leads to a formulation in terms of the dipole-dipole response function plus a divergent term which describes intraband transitions for metallic systems. The current-based approach is instead exact at $\mathbf{q} = \mathbf{0}$. In practice, however, one needs to impose the conductivity sum rule in a way which suppresses the intraband transitions at $\mathbf{q} = \mathbf{0}$, thus making the small $\mathbf{q}$ expansion needed for metallic systems also in the current based approach.

When gapped systems are considered there are no intraband transitions and the two approaches are formally equivalent once the conductivity sum rule is imposed in the current-based approach. On the other hand, we showed that the formal equivalence of the approaches may be lost in practical calculations when the strategies usually employed in the density-based approach to include smearing, quasiparticle lifetimes and the electron-hole interaction are naively applied to the current-based approach. The smearing is included straightforwardly in the density-based approach by replacing the real frequency with an imaginary frequency. However, a careless extension of this recipe within the current-based approach leads to unphysical features in the optical spectrum. We showed how correctly include the smearing by redefining the dielectric function and the conductivity sum rule. The inclusion of lifetimes, quasiparticle corrections, and excitonic effects correspond to a change in the underlying Hamiltonian. Therefore the velocity operator, which enters the definition of the current-current response function, has to be modified accordingly. We noted instead that the expression for the excitonic velocity operator reported in several published works is incorrect. In this work we thus report the correct general definition for the velocity operator when complex energies, quasiparticle corrections, and excitonic effects are taken into account.

APPENDIX A: FOURIER TRANSFORM IN PERIODIC BOUNDARY CONDITIONS

Here we explicitly introduce the Fourier transform in periodic boundary conditions (PBC). To make the derivation more clear, we use, just for the present appendix, different symbols for the different functions in real and reciprocal space associated to a given observable O . We start from the general definition:

$$O(\mathbf{x}) = \int \frac{d^3\mathbf{k}}{(2\pi)^3} \mathcal{O}(\mathbf{k}) e^{i\mathbf{k}\cdot\mathbf{x}}, \quad (\text{A1a})$$

$$\mathcal{O}(\mathbf{k}) = \int d^3\mathbf{x} O(\mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}}. \quad (\text{A1b})$$

We then divide the space in a series of microscopic unit cells with volume V , which are periodically repeated and we use $\mathbf{x} = \mathbf{r} + \mathbf{R}$ with $\mathbf{r}$ restricted to the volume V centered at $\mathbf{R} = \mathbf{0}$. Accordingly, the reciprocal space is separated in two parts with $\mathbf{G}$ defined by $\mathbf{G} \cdot \mathbf{R} = 2\pi n$, where n is any integer number, and $\mathbf{q} = \mathbf{k} - \mathbf{G}$ restricted to the first Brillouin Zone with volume $\Omega = (2\pi)^3 / V$. Then the Fourier transform becomes

$$O(\mathbf{R} + \mathbf{r}) = \sum_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} \int_{\Omega} \frac{d^3\mathbf{q}}{(2\pi)^3} \mathcal{O}(\mathbf{q} + \mathbf{G}) e^{i\mathbf{q}\cdot(\mathbf{r}+\mathbf{R})}, \quad (\text{A2a})$$

$$\mathcal{O}(\mathbf{q} + \mathbf{G}) = \sum_{\mathbf{R}} e^{-i\mathbf{q}\cdot\mathbf{R}} \int_V d^3\mathbf{r} O(\mathbf{r} + \mathbf{R}) e^{-i(\mathbf{q}+\mathbf{G})\cdot\mathbf{r}}. \quad (\text{A2b})$$

a. Periodic quantities

A periodic function $O(\mathbf{r})$ is characterized by the property $O(\mathbf{R} + \mathbf{r}) = O(\mathbf{r})$. Substitution of this identity into Eq. (A2b) leads to

$$\begin{aligned} \mathcal{O}(\mathbf{q} + \mathbf{G}) &= \sum_{\mathbf{R}} e^{-i\mathbf{q}\cdot\mathbf{R}} \int_V d^3\mathbf{r} O(\mathbf{r}) e^{-i(\mathbf{q}+\mathbf{G})\cdot\mathbf{r}} \\ &= \Omega \delta(\mathbf{q}) \int_V d^3\mathbf{r} O(\mathbf{r}) e^{-i\mathbf{G}\cdot\mathbf{r}} \\ &= \Omega \delta(\mathbf{q}) \tilde{\mathcal{O}}(\mathbf{G}), \end{aligned} \quad (\text{A3})$$

i.e., the Fourier transform of a periodic function has nonzero components only for $\mathbf{q} = \mathbf{0}$. We can use this result in Eq. (A2a) to obtain

$$\begin{aligned} O(\mathbf{R} + \mathbf{r}) &= \Omega \sum_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} \int_{\Omega} \frac{d^3\mathbf{q}}{(2\pi)^3} \delta(\mathbf{q}) \mathcal{O}(\mathbf{G}) e^{i\mathbf{q}\cdot(\mathbf{r}+\mathbf{R})} \\ &= \frac{1}{V} \sum_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} \tilde{\mathcal{O}}(\mathbf{G}) = O(\mathbf{r}). \end{aligned} \quad (\text{A4})$$

Thus the Fourier transforms in Eq. (A2) reduce to

$$O(\mathbf{r}) = \frac{1}{V} \sum_{\mathbf{G}} \tilde{O}(\mathbf{G}) e^{i\mathbf{G}\cdot\mathbf{r}}, \quad (\text{A5a})$$

$$\tilde{O}(\mathbf{G}) = \int_V d^3\mathbf{r} O(\mathbf{r}) e^{-i\mathbf{G}\cdot\mathbf{r}}, \quad (\text{A5b})$$

and the macroscopic part of a periodic quantity, i.e., its average over the unit cell, is $\tilde{O}(\mathbf{G} = \mathbf{0})/V$.

b. Macroscopic quantities

Here, we are interested in processes in which the transferred momentum $\mathbf{q} + \mathbf{G}$ is small. Let us therefore consider a (non periodic) function for which, in reciprocal space, only the $\mathbf{G} = \mathbf{0}$ component is nonzero, i.e., $\mathcal{O}(\mathbf{q} + \mathbf{G}) = \delta_{\mathbf{G},\mathbf{0}} \bar{\mathcal{O}}(\mathbf{q})$. Its Fourier transform in real space, given by

$$\begin{aligned} O(\mathbf{R} + \mathbf{r}) &= \sum_{\mathbf{G}} e^{i\mathbf{G}\cdot\mathbf{r}} \int_{\Omega} \frac{d^3\mathbf{q}}{(2\pi)^3} \delta_{\mathbf{G},\mathbf{0}} \bar{\mathcal{O}}(\mathbf{q}) e^{i\mathbf{q}\cdot(\mathbf{r}+\mathbf{R})} \\ &= \int_{\Omega} \frac{d^3\mathbf{q}}{(2\pi)^3} \bar{\mathcal{O}}(\mathbf{q}) e^{i\mathbf{q}\cdot(\mathbf{r}+\mathbf{R})} \end{aligned} \quad (\text{A6})$$

depends both on $\mathbf{R}$ and $\mathbf{r}$, but with a smooth dependence on $\mathbf{r}$ since it has no fast oscillating $\mathbf{G}$ component. Its inverse Fourier transform is

$$\bar{\mathcal{O}}(\mathbf{q}) = \sum_{\mathbf{R}} e^{-i\mathbf{q}\cdot\mathbf{R}} \left(\int_V d^3\mathbf{r} e^{-i\mathbf{q}\cdot\mathbf{r}} O(\mathbf{R} + \mathbf{r}) \right). \quad (\text{A7})$$

If $e^{-i\mathbf{q}\cdot\mathbf{r}} \simeq 1$, we can neglect the $\mathbf{r}$ dependence and consider

$$\bar{\mathcal{O}}(\mathbf{R}) \equiv \frac{1}{V} \int_V d^3\mathbf{r} O(\mathbf{R} + \mathbf{r}). \quad (\text{A8})$$

We thus obtain

$$\bar{\mathcal{O}}(\mathbf{R}) \simeq \int_{\Omega} \frac{d^3\mathbf{q}}{(2\pi)^3} \bar{\mathcal{O}}(\mathbf{q}) e^{i\mathbf{q}\cdot\mathbf{R}}, \quad (\text{A9a})$$

$$\bar{\mathcal{O}}(\mathbf{q}) \simeq V \sum_{\mathbf{R}} \bar{\mathcal{O}}(\mathbf{R}) e^{-i\mathbf{q}\cdot\mathbf{R}}. \quad (\text{A9b})$$

The relation $e^{-i\mathbf{q}\cdot\mathbf{r}} \simeq 1$ holds for small $\mathbf{q}$, i.e., in the “macroscopic limit”, where one can consider the volume V as infinitesimal ($V \rightarrow d^3\mathbf{R}$ and $\Omega \rightarrow \mathbb{R}^3$) and $\mathbf{R}$ becomes a continuous variable. Indeed we can assume $\mathbf{q}$ or small V if $2\pi/q \gg V^{1/3}$. In this limit, materials are considered as a continuum, their atomistic structure is neglected and the macroscopic integrals used to describe electromagnetism in classical media are recovered. Instead for short wavelengths, i.e., $2\pi/q \ll V^{1/3}$, the atomistic structure can never be neglected and one is forced to use Eqs. (A6) and (A7) when computing the response induced at $\mathbf{G} = \mathbf{0}$ in PBC.

APPENDIX B: FULL DIELECTRIC TENSOR

In general, the dielectric tensor $\underline{\underline{\varepsilon}}^M(\mathbf{q}, \omega)$ can be decomposed into a longitudinal component, a transverse component, and mixed components as

$$\underline{\underline{\varepsilon}}^M(\mathbf{q}, \omega) = \begin{pmatrix} \varepsilon^L & \varepsilon^{LT} \\ \varepsilon^{TL} & \varepsilon^T \end{pmatrix}. \quad (\text{B1})$$

For isotropic systems, in particular, there exist only two independent components, i.e., the longitudinal one (ε^L) and transverse one (ε^T), so that the dielectric function reads

$$\varepsilon_{ij}^M(\mathbf{q}, \omega) = \varepsilon^L(\mathbf{q}, \omega) \frac{q_i q_j}{|\mathbf{q}|^2} + \varepsilon^T(\mathbf{q}, \omega) \left(\delta_{ij} - \frac{q_i q_j}{|\mathbf{q}|^2} \right). \quad (\text{B2})$$

The longitudinal component describes the response to longitudinal fields, which are involved, for example, in electron energy-loss experiments, where the scattering cross-section of an electron traversing a medium is proportional to $-\text{Im}\{1/\varepsilon^L(\mathbf{q}, \omega)\}$. The transverse component describes the response to optical fields, which are characterized by small $q \approx \omega/c \approx 0$. In the long-wavelength limit $q \rightarrow 0$, the two quantities are equal [56,57], thus optical and energy-loss measurements contain the same physical information. In particular for cubic symmetry, we have

$$\lim_{\mathbf{q} \rightarrow \mathbf{0}} \varepsilon^M(\mathbf{q}, \omega) = \varepsilon^M(\omega) \underline{\underline{1}}. \quad (\text{B3})$$

Since in the present manuscript we only deal with longitudinal perturbations and longitudinal external fields, when we write a scalar dielectric function this is understood to be its longitudinal component, i.e., $\varepsilon(\mathbf{q}, \omega) = \varepsilon^L(\mathbf{q}, \omega)$. The same applies to other quantities such as the current-current response function $\chi_{jj}(\mathbf{q}, \omega) = \chi_{\mathbf{j}\mathbf{j}}^L(\mathbf{q}, \omega) = \chi_{j^L j^L}(\mathbf{q}, \omega)$, the external potential $A(\mathbf{q}, \omega) = A^L(\mathbf{q}, \omega)$, the current $j(\mathbf{q}, \omega) = \mathbf{j}^L(\mathbf{q}, \omega)$, the polarization $P(\mathbf{q}, \omega) = \mathbf{P}^L(\mathbf{q}, \omega)$, and the dipoles $d_{\mathbf{q}} = \mathbf{d}_{\mathbf{q}}^L$.

APPENDIX C: GAUGES

The scalar and vector potentials $\phi(\mathbf{x}, t)$ and $\mathbf{A}(\mathbf{x}, t)$, respectively, describe a general electromagnetic field by

$$\begin{aligned} \mathbf{E}(\mathbf{x}, t) &= -c^{-1} \partial_t \mathbf{A}(\mathbf{x}, t) - \nabla \phi(\mathbf{x}, t), \\ \mathbf{B}(\mathbf{x}, t) &= c^{-1} \nabla \times \mathbf{A}(\mathbf{x}, t). \end{aligned} \quad (\text{C1})$$

The electromagnetic field is invariant under the gauge transformations

$$\begin{aligned} \phi(\mathbf{x}, t) &\rightarrow \phi(\mathbf{x}, t) - c^{-1} \partial_t \Lambda(\mathbf{x}, t), \\ \mathbf{A}(\mathbf{x}, t) &\rightarrow \mathbf{A}(\mathbf{x}, t) + \nabla \Lambda(\mathbf{x}, t), \end{aligned} \quad (\text{C2})$$

Here, $\Lambda(\mathbf{x}, t)$ is a differentiable, but, otherwise, arbitrary function of $\mathbf{x}$ and t . Notice that in quantum mechanics the gauge transformation also modifies the wave function phase as

$$\psi(\mathbf{x}, t) \rightarrow \psi(\mathbf{x}, t) e^{i \frac{\Lambda(\mathbf{x}, t)}{c}}.$$

One can use the gauge freedom to map a problem in an equivalent one, which is maybe easier to solve. For example, one can completely gauge transform the scalar potential ϕ into a vector potential of the form

$$\mathbf{A}(\mathbf{x}, t) = c \int_0^t \nabla \phi(\mathbf{x}, t') dt', \quad (\text{C3})$$

using $\Lambda(\mathbf{x}, t) = c \int_0^t \phi(\mathbf{x}, t') dt'$. This is the Weyl gauge. Such a vector potential, being expressed as the gradient of a scalar, is longitudinal, i.e., it describes a longitudinal vector field, since its Fourier transform is parallel to $\mathbf{q}$ for any $\mathbf{q}$. Using $\Lambda(\mathbf{r}, t) = -\int A^L(\mathbf{x}', t) d^3\mathbf{x}'$, one can gauge transform the longitudinal

component of $\mathbf{A}(\mathbf{x}, t)$ to a scalar potential as

$$\phi(\mathbf{x}, t) = c^{-1} \int \partial_t A^L(\mathbf{x}', t) d^3 \mathbf{x}'. \quad (\text{C4})$$

This is the Coulomb gauge defined by $\nabla \cdot \mathbf{A}(\mathbf{x}, t) = 0$. In the dipole approximation, i.e., $\mathbf{E}(\mathbf{x}, t) \approx \mathbf{E}(\mathbf{0}, t)$, the two gauges reduce to the length and the velocity gauge.

Gauge transformation affects only the potentials describing longitudinal fields as it is clear if Eq. (C2) is written in Fourier space. Indeed, the transverse part of the vector potential is gauge independent and can never be described in terms of a scalar potential.

APPENDIX D: MACROSCOPIC RESPONSE FUNCTIONS

In a system with translation invariance symmetry only for $\mathbf{x} = \mathbf{R}$, the longitudinal potentials $\delta\phi^{\mathbf{G}'}(\mathbf{q}, \omega)$ and $\delta A^{\mathbf{G}'}(\mathbf{q}, \omega)$ in general induce variations at any $\mathbf{q} + \mathbf{G}$ component with $\mathbf{G}$ also different from $\mathbf{G}'$ (we write here the dependence on $\mathbf{G}$ as a superscript for convenience). Indeed, we can formally write the component of the induced density and current density linear in the perturbing potentials of form (2a) and (2b) (using either the length or the velocity gauge) as

$$\begin{aligned} \delta\rho^{\mathbf{G}}(\mathbf{q}, \omega) &= \sum_{\mathbf{G}'} \chi_{\rho\rho}^{\mathbf{G}, \mathbf{G}'}(\mathbf{q}, \omega) \delta\phi^{\mathbf{G}'}(\mathbf{q}, \omega), \\ c\delta j^{\mathbf{G}}(\mathbf{q}, \omega) &= \sum_{\mathbf{G}'} \chi_{j\rho}^{\mathbf{G}, \mathbf{G}'}(\mathbf{q}, \omega) \delta\phi^{\mathbf{G}'}(\mathbf{q}, \omega) \\ &\quad + \frac{1}{V} \sum_{\mathbf{G}'} \rho_0^{\mathbf{G}-\mathbf{G}'} \delta A^{\mathbf{G}'}(\mathbf{q}, \omega), \end{aligned} \quad (\text{D1})$$

where $\mathbf{q}$ is now restricted to the first Brillouin zone, $\mathbf{G}$ is a reciprocal lattice vector, and

$$\begin{aligned} \chi_{ab}(\mathbf{q}, \mathbf{q}', \omega) &= \frac{1}{(2\pi)^3} \int d\mathbf{r} e^{-i\mathbf{q}\cdot\mathbf{r}} \int d\mathbf{r}' e^{-i\mathbf{q}'\cdot\mathbf{r}'} \\ &\quad \times \int_0^\infty d\tau \chi_{ab}(\mathbf{r}, \mathbf{r}', \tau). \end{aligned} \quad (\text{D2})$$

If we consider a perturbation with only the $\mathbf{G}' = \mathbf{0}$ component, i.e., $\delta\phi^{\mathbf{G}'}(\mathbf{q}, \omega) = \delta\phi(\mathbf{q}, \omega) \delta_{\mathbf{G}', \mathbf{0}}$ and $\delta A^{\mathbf{G}'}(\mathbf{q}, \omega) = \delta A(\mathbf{q}, \omega) \delta_{\mathbf{G}', \mathbf{0}}$, and look for the variation of the macroscopic induced density and current density, i.e., their $\mathbf{G} = \mathbf{0}$ Fourier component, we arrive at (5a) and (5b).

APPENDIX E: INTRABAND CONTRIBUTION TO C

Following similar steps as in Ref. [14], the intraband contribution to $\bar{\chi}_{dd}^{\text{IP}}$

becomes

$$\begin{aligned} \chi_{dd}^{\text{IP, intra}}(\mathbf{q}, \omega) &= \frac{1}{8\pi^3} \sum_i \int_{S_i} \frac{d^2 \mathbf{k}}{|\mathbf{v}_{i\mathbf{k}}^F|} j_{(i\mathbf{k}+\mathbf{q}; \mathbf{k})}^{p, \text{IP}} j_{(i\mathbf{k}; \mathbf{k}+\mathbf{q})}^{p, \text{IP}} \\ &\quad \times \frac{1}{\omega^2} \frac{(\omega/q)^2}{(\mathbf{v}_{i\mathbf{k}}^F \cdot \hat{\mathbf{q}})^2 - (\omega^+/q)^2}, \end{aligned} \quad (\text{E1})$$

where $\sum_{\mathbf{k}}$ has been replaced by $V/(2\pi)^3 \int d\mathbf{k}$ and the integration over the k space reduced to an integral over the sheets S_i of the Fermi surface originating by the partially occupied bands i . Here, $\mathbf{v}_{i\mathbf{k}}^F$ is the Fermi velocity. For the frequency-dependent factor, we can use the Cauchy theorem and write

$$\begin{aligned} &\frac{(\omega/q)^2}{(\mathbf{v}_{i\mathbf{k}}^F \cdot \hat{\mathbf{q}})^2 - (\omega^+/q)^2} \\ &= \mathcal{P} \frac{(\omega/q)^2}{(\mathbf{v}_{i\mathbf{k}}^F \cdot \hat{\mathbf{q}})^2 - (\omega/q)^2} + \frac{1}{\omega^2} i\pi (\omega/q)^2 \\ &\quad \times [\delta(\mathbf{v}_{i\mathbf{k}}^F \cdot \hat{\mathbf{q}} - \omega/q) + \delta(\mathbf{v}_{i\mathbf{k}}^F \cdot \hat{\mathbf{q}} + \omega/q)]. \end{aligned} \quad (\text{E2})$$

In optical experiments ω/q is of the order of the velocity of light c .²⁰ Therefore a Drude-like peak in the absorption can be described only if $|\mathbf{v}_{n\mathbf{k}}^F| \approx c$. At the IP level, using real energies, this never happens; therefore the imaginary part in Eq. (E2) is zero and the real part reduces to -1 in the limit of $q \rightarrow 0$ (and finite ω). In this case, the intraband contribution to the dielectric function is real and reads

$$\begin{aligned} \lim_{\mathbf{q} \rightarrow 0} \varepsilon[\chi_{dd}^{\text{IP, intra}}](\mathbf{q}, \omega) &= \varepsilon^{\text{IP, intra}}(\omega) \\ &= \frac{-1}{\pi^2 \omega^2} \lim_{\mathbf{q} \rightarrow 0} \sum_i \int_{S_i} \frac{d^2 \mathbf{k}}{|\nabla_{\mathbf{k}} \epsilon_{i\mathbf{k}}|} j_{(i\mathbf{k}+\mathbf{q}; \mathbf{k})}^{p, \text{IP}} j_{(i\mathbf{k}; \mathbf{k}+\mathbf{q})}^{p, \text{IP}}. \end{aligned} \quad (\text{E3})$$

In the excitonic case, the treatment of the intraband contribution is more involved and requires also the Taylor expansion of $E_{\lambda}(\mathbf{q})$ and $A_{\lambda, \mathbf{q}}$.

²⁰The direction of the $\mathbf{q} \rightarrow \mathbf{0}$ limit is a delicate point. Indeed, the $(\mathbf{0}, 0)$ point in the $(\mathbf{q}, \omega)$ plane is nonanalytic, i.e., the value of the dielectric function depends on the direction of the limit $(\mathbf{q}, \omega) \rightarrow (\mathbf{0}, 0)$. This direction is determined by the experiment we would like to describe. In optical experiments, the direction of interest is $\omega = c\mathbf{q}$. Other directions in the $(\mathbf{q}, \omega)$ plane may be of interest. For example, in electron-energy loss experiments, one measures the inverse dielectric function $\varepsilon^{-1}(\mathbf{q}, \omega)$ at fixed momentum $\mathbf{q}_{\text{exp}}$. The line $\mathbf{q} = \mathbf{q}_{\text{exp}}$ always crosses the $\mathbf{v}^F(\mathbf{q})$ line, thus a peak must always appear if we derive $\varepsilon(\mathbf{q}, \omega)$ from the computed electron energy loss function at $\mathbf{q}_{\text{exp}}$. Therefore, for $\mathbf{q}_{\text{exp}} \rightarrow \mathbf{0}$, we always obtain the Drude-like tail in the absorption spectrum, also without smearing.
