HIGHLIGHTS
- 3 types of Ti₃C₂ electrodes were prepared: clay, delaminated and CNT composite.
- Capacitance up to 245 F cm⁻³ in 1 M EMITFSI solution in acetonitrile was achieved.
- Imidazolium (EMI⁺) ions intercalation was demonstrated by in situ XRD.

GRAPHICAL ABSTRACT

ABSTRACT

Pseudocapacitive materials that store charges by fast redox reactions are promising candidates for designing high energy density electrochemical capacitors. MXenes – recently discovered two-dimensional carbides, have shown excellent capacitance in aqueous electrolytes, but in a narrow potential window, which limits both the energy and power density. Here, we investigated the electrochemical behavior of Ti₃C₂ MXene in 1M solution of 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)-imide (EMITFSI) in acetonitrile and two other common organic electrolytes. This paper describes the use of clay, delaminated and composite Ti₃C₂ electrodes with carbon nanotubes in order to understand the effect of the electrode architecture and composition on the electrochemical performance. Capacitance values of 85 F g⁻¹ and 245 F cm⁻³ were obtained at 2 mV s⁻¹, with a high rate capability and good cyclability. In situ X-ray diffraction study reveals the intercalation of large EMI⁺ cations into MXene, which leads to increased capacitance, but may also be the rate limiting factor that determines the device performance.

1. Introduction

Electrochemical capacitors (ECs) are commercial devices used for high power delivery applications [1,2]. They typically utilize either porous carbon materials or pseudocapacitive materials for electrostatic or redox energy storage, respectively [3,4]. In the latter, the charge is stored by fast redox reactions at the surface of materials such as MnO₂, RuO₂, Nb₂O₅ or MoO₃ [5–8]. Recently, energy storage based on ion intercalation into two-dimensional (2D) materials has attracted much attention because of promising results with up to 375 F g⁻¹ in KOH or 200 F g⁻¹ in organic electrolyte for functionalized graphene [9,10].
A new family of two-dimensional materials called MXenes has emerged as promising electrodes for energy storage devices such as batteries [11–15], metal ion (Li⁺, Na⁺) capacitors [16–18] and ECs [19–22]. MXenes are synthesized by selective etching of the A layer from the conductive ternary carbide family of MAX phases [23]. Of the MXene family, Ti₃C₂ was the first discovered and is the most studied to date. First studies of Ti₃C₂ as electrode material in supercapacitors showed capacities up to 100 F g⁻¹ for intercalation of cations such as Li⁺, Mg²⁺ or Al³⁺ in aqueous electrolytes [19]. Aside, MXene performance can be greatly improved by tuning the surface functional groups, delamination or addition of carbon nanoparticles [14,21,22]. Delaminated Ti₃C₂ electrodes containing carbon nanotubes have also shown noteworthy performance in lithium ion batteries, as well as in aqueous supercapacitors with capacity up to 430 mAh g⁻¹ and capacitance of 140 F g⁻¹, respectively [14,22]. The modification of the chemistry of the surface groups through a new “clay” synthesis route led to a 2-fold increase in volumetric capacitance (up to 900 F cm⁻³) in sulfuric acid electrolyte due to dense packing of 2D MXene sheets combined with their accessibility due to pre-intercalation of ions during the synthesis [20]. The role of pseudocapacitance in these high values was confirmed by showing a reversible change in the oxidation state of titanium atoms in MXene [24].

However, MXene has been investigated as electrode material for ECs mainly in aqueous electrolytes, which show a limited potential window due to water electrolysis. Moreover, oxidation of Ti₃C₂ under high anodic potentials in aqueous electrolytes further limits its use to cathodes of asymmetric devices. As both the energy and the power density increase with the square of the potential window, its expansion is one of the key challenges for designing SCs based on MXenes. The energy storage mechanism was studied by in situ X-ray diffraction (XRD) patterns of the CNT-Ti₃C₂ electrodes. The MXene performance can be greatly improved by tuning the surface functional groups through a new “clay” synthesis route led to a 2-fold increase in volumetric capacitance (up to 900 F cm⁻³) in sulfuric acid electrolyte due to dense packing of 2D MXene sheets combined with their accessibility due to pre-intercalation of ions during the synthesis [20]. The role of pseudocapacitance in these high values was confirmed by showing a reversible change in the oxidation state of titanium atoms in MXene [24].

### 2. Experimental

#### 2.1. Electrode preparation

Ti₃C₂ was synthesized by selectively etching the aluminum layer out of the Ti₃AlC₂ MAX phase in a 6M HCl/LiF solution at 35 °C for 24 h [20]. The obtained material was then washed with distilled water. MXene samples after synthesis were terminated with OH, O and F and we add Tₐ to the Ti₃C₂ formula to show those surface terminations. Full delamination of Ti₃C₂⁵Tₐ was obtained by ultrasonication for 1 h in distilled water. A composite material was prepared by mixing the colloidal solution of delaminated Ti₃C₂ with 20 wt. % of multiwalled carbon nanotubes (MWCNT C100, Graphistrength) which have specific surface area of 175 m² g⁻¹. The as-synthesized Ti₃C₂[Tₐ] was then dried, the films were easily removed from the membrane to obtain the freestanding Ti₃C₂[Tₐ] films without binder. The electrodes were prepared by cutting the films into rectangles with a razor blade. The thicknesses were measured from scanning electron microscope observations and Ti₃C₂[Tₐ] and Ti₃C₂[Tₐ] film densities were calculated to be 2.3 g cm⁻³, 3.0 g cm⁻³ and 2.9 g cm⁻³, respectively.

#### 2.2. Electrochemical testing

Three-electrode Swagelok® cells were used with Ti₃C₂ as working electrode, an Ag wire as a pseudo-reference electrode and a commercial activated carbon (YP17 Kuraray, Japan) as counter electrode. The cell was assembled using a 1M electrolyte (tetraethylammonium tetrafluoroborate, Fluksa) and 0.1M TFA (trifluoromethanesulfonic acid) in acetonitrile (Acros Organics). Electrochemical impedance spectroscopy (EIS) was performed between 0.1 Hz and 1 MHz.

### 3. Results and discussion

Fig. 1 shows cross-section SEM images of electrode materials. The MXene layers can be rolled and sheared, forming a freestanding flexible electrode [20,21]. Fully delaminated MXene electrodes, denoted as d-Ti₃C₂Tₐ (Fig. 1b), were prepared for improving the electrochemical performance by taking advantage of a higher specific surface area (SSA) resulting from delamination. The SSA values were 23 m² g⁻¹ for multilayered Ti₃C₂ and 98 m² g⁻¹ for delaminated Ti₃C₂ measured elsewhere by nitrogen gas sorption analysis [12]. However, previous studies demonstrated that restacking of delaminated MXene layers forming a dense MXene “paper” with in-plane alignment of MXene sheets limits the accessibility of electrolyte ions. Such restacking issue can be prevented by addition of carbon nanoparticles [14,22]. Accordingly, composite electrodes were prepared by mixing appropriate amounts of d-Ti₃C₂Tₐ and MWCNTs. The SSA obtained by nitrogen gas sorption analysis was 70 m² g⁻¹ for the CNT-Ti₃C₂Tₓ. Fig. 1c–d shows SEM images of a cross-section of the CNT-Ti₃C₂Tₓ composite electrode, where CNTs are homogeneously spread between the Ti₃C₂ layers since no aggregates can be seen. Aside preventing restacking, CNT addition is known to increase the conductivity of the electrodes [14,22,25–27].

These measurements were done using a three-electrode Swagelok cell.
based electrodes at 20 mV s$^{-1}$ in 1M EMITFSI in acetonitrile. The electrochemical signatures of the three samples appear to be similar, characterized by a capacitive envelope and a set of redox peaks around −0.2 V and −0.4 V vs. Ag. The potential difference between the oxidation and the reduction peaks, associated with kinetics and ohmic limitations, changes from one electrode to another. The smaller difference is observed for CNT-Ti$_3$C$_2$T$_x$ that can be associated in a first approach to a faster diffusion path, thanks to the addition of CNTs. Ti$_3$C$_2$T$_x$ shows similar electrochemical signature with a slightly larger overpotential and d-Ti$_3$C$_2$T$_x$ shows the largest overpotential and more resistive behavior, possibly due to the restacking of delaminated layers during electrode preparation. The potential range (1.8 V) is narrower than expected from this electrolyte, but could be explained by water trapped between Ti$_3$C$_2$ layers, responsible for electrolyte reaction at the extrema of the potential range visible at low scan rates.

The change of the capacitance (calculated from the integration of the charge during CV measurements) with the potential scan rate is shown Fig. 2d. Capacitance up to 245 F cm$^{-2}$ (85 F g$^{-1}$) was obtained at 2 mV s$^{-1}$ for CNT-Ti$_3$C$_2$, with 75% capacitance retention at 100 mV s$^{-1}$ (50% for d-Ti$_3$C$_2$T$_x$). This performance highlights a fairly high power capability of the electrodes, which is assumed to originate from the open 2D structure of the material and the associated high accessibility of the surface to ions. The lower rate performance of d-Ti$_3$C$_2$ could be attributed to poor charge percolation.

The electrochemical impedance spectroscopy measurements (Fig. 3) on the three different samples at a bias voltage of 0.5 V (OCV) suggest that the addition of MWCNT greatly improves the charge percolation of the electrode. Additionally, there is little to no influence of MWCNTs on the electronic conductivity of the electrode, as can be seen from the constant value of the high-frequency resistance. This can be explained by a much higher conductivity of metallic Ti$_3$C$_2$T$_x$ electrode films (∼2000 S cm$^{-1}$) compared to conventional activated carbon, oxide or even graphene electrodes.

Fig. 4a–c shows the galvanostatic charge–discharge curves obtained at 1 A g$^{-1}$ of the three electrodes. The curves are almost linear but contain a slight change in their slopes which correspond to the redox peaks identified previously. It appears that the electrodes exhibit pseudo-capacitive behavior. Also, a 5–10 times lower specific surface area of MXene [19] compared to activated carbons [4] would lead to a very low capacitance without contribution of charge-transfer processes. Fig. 4d shows the cycle life for the different electrodes, at 1 A g$^{-1}$. CNT-Ti$_3$C$_2$T$_x$ shows a good stability, with 90% capacitance retention after 1000 cycles. Ti$_3$C$_2$T$_x$ and d-Ti$_3$C$_2$T$_x$ show a lower stability and faster capacitance decrease during cycling, as well as a lower coulombic efficiency.

The energy storage mechanism was investigated by recording in situ XRD patterns at different potentials (Fig. 5a). The comparison of patterns indicates that depending on the applied potential two different sets of Bragg peaks are observed and that the phase change occurs at the same potential were the set of redox peaks appears in the CV (Fig. 2c). This shows that intercalation/deintercalation processes follow a reversible two-phase mechanism, which differs from the progressive and continuous intercalation process previously observed for MXenes materials in aqueous supercapacitor [19] and metal-ions capacitors [16,17]. Each set of Bragg peaks can be indexed, in agreement with Ghidiu et al. [20], using the (001) diffraction planes of Ti$_3$C$_2$ which are characteristic of the interlayer space. On the basis of the diffraction angle of (002) Bragg peaks (Fig. 3b), it can be deduced that in the −0.8 V to −0.5 V potential range, the interlayer distance is 1.3 Å larger than at potentials above −0.5 V and should correspond to the intercalation and de-intercalation of ions from the electrolyte into Ti$_3$C$_2$T$_x$.

Considering the low value of the intercalation potential, one can assume in a first approximation that the expansion is due to the intercalation of the EM$^+$ cations between Ti$_3$C$_2$ layers and the shrinkage is attributed to its de-intercalation. Reversible intercalation of organic ions accompanied by peaks in CVs was observed for porous carbon electrodes, when the ion size was somewhat larger than the pore size [29]. Interestingly when cycled within the 0.1 V−1 V potential range, Ti$_3$C$_2$T$_x$ capacitance quickly decreases with the cycle number, while it is more stable when cycled between −0.8 V and 0.1 V, as shown Fig. 6. This suggests that the capacitive behavior observed above 0 V is associated with a redox process at negative potentials. In other 2D materials, it is admitted that the intercalation of ions can form a pillared structure [18,30–32]. It is possible that cycling exclusively in the positive region causes the structure to collapse.

Further evidence that the redox reaction is due to the intercalation of cations is provided by comparison of the CVs of CNT-Ti$_3$C$_2$T$_x$ in 1M solutions of EMITFSI, EMIBF$_4$ and TEABF$_4$ in acetonitrile. Fig. 7a shows the CV of the CNT-Ti$_3$C$_2$T$_x$ electrode in 1 M EMIBF$_4$ in acetonitrile electrolyte (a smaller anion but the same cation as in Fig. 2). The electrochemical signature is similar to that obtained in 1M EMITFSI in acetonitrile electrolyte (Fig. 2); more specifically, we note the presence of a set of redox peaks at the same potential. Fig. 7b shows the CV of the CNT-Ti$_3$C$_2$T$_x$ electrode in 1 M TEABF$_4$ in acetonitrile electrolyte. When replacing the “planar” EM$^+$ cation with the larger and more “spherical” TEA$^+$ cation, the electrochemical response is drastically changed. The reduction (intercalation) peak is present at a lower potential (−1 V vs Ag wire), but the reaction seems irreversible with an oxidation wave shifted to about 0.5 V. Probably, large TEA$^+$ ions are stuck between MXene sheets after intercalation, decreasing the reversibility of the process, but also contributing to pillaring. These measurements suggest that the intercalation/deintercalation of the EM$^+$ cation is responsible for the reversible redox process occurring at −0.4 V vs. Ag. This hypothesis should be further confirmed by other in situ characterization techniques, such as electrochemical quartz crystal microbalance [33] or nuclear magnetic resonance [34].

4. Conclusions

The electrochemical behavior of Ti$_3$C$_2$T$_x$ as an electrochemical capacitor electrode in organic electrolytes has been investigated. Capacitance up to 32 F g$^{-1}$ was obtained for as-produced Ti$_3$C$_2$T$_x$ MXene clay and improved to 85 F g$^{-1}$ by delamination and addition of carbon nanotubes. Intercalation of large EM$^+$ cations between the layers of Ti$_3$C$_2$ has been demonstrated suggesting that other large or multivalent cations may be similarly intercalated into
MXenes from organic electrolyte solutions. Ti$_3$C$_2$T$_x$ capacitance was increased 3-fold, up to 85 F g$^{-1}$ and 245 F cm$^{-3}$ at 2 mV s$^{-1}$ by using carbon nanotubes as an additive to improve ion accessibility to the active material. The CNT/Ti$_3$C$_2$T$_x$ electrodes show a good rate performance and good cycle life stability. Considering that this is the first report on capacitance of Ti$_3$C$_2$ in organic electrolytes used in supercapacitors and that Ti$_3$C$_2$ is only one of more than a dozen of already synthesized MXenes, there are good reasons to expect further improvement in capacitance as the optimal MXene-
