HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
8000 years of vegetation history in the northern Iberian Peninsula inferred from the palaeoenvironmental study of the Zalama ombrotrophic bog (Basque-Cantabrian Mountains, Spain)

SEBASTIÁN PÉREZ-DÍAZ, JOSÉ ANTONIO LÓPEZ-SÁEZ, XABIER PONTEVEDRA-POMBAL, MARTÍN SOUTO-SOUTO AND DIDIER GALOP

This paper focuses on pollen, spores, non-pollen palynomorphs (NPPs) and certain geochemical elements from the ombrotrophic blanket bog of Zalama (Basque-Cantabrian Mountains, northern Iberian Peninsula), with the support of a robust chronology based on 17 AMS $^{14}$C dates. The main results related to the last 8000 years show that, during the early middle Holocene, pines and deciduous forests were the most extensive tree formations. At the beginning of the subsequent period, pines reach 44%, showing regional presence, whereas after 7600 cal. a BP, deciduous forests were particularly abundant. From c. 6500 cal. a BP the pollen diagram constructed from our samples shows the first anthropogenic evidence, linked with the new economic practices related to the Neolithic of the Basque-Cantabrian Mountains. From 3300 cal. a BP the expansion of Fagus sylvatica is particularly clear, and has since then become one of the dominant forest species in this region. We also discuss the Holocene evolution of other noteworthy plant communities in southwestern Europe, such as Taxus baccata, Juglans and shrublands.

Peatlands have long been studied in the scientific literature from two basic perspectives: (i) their function as ‘islands of biodiversity’, i.e. refuges of particularly vulnerable species, and (ii) their use as palaeoenvironmental archives. These natural deposits can be interpreted from many different viewpoints, very interesting for a proper understanding of past climatic, biotic and cultural records (Barber 1993; Lappalainen 1996; Chambers & Daniell 2010; de Jong et al. 2010). In this sense, ombrotrophic bogs, such as the Zalama peat bog presented in this work, are especially noteworthy deposits. Their water regime and nutrient supply are derived directly and exclusively from precipitation (Lindsay 1995). As a result, they are oligotrophic and usually highly acidic environments, ensuring good overall preservation of organic matter (Pontevedra-Pombal et al. 2006, 2013). These characteristics are critical in making ombrotrophic peatlands excellent palaeoenvironmental archives, which yield data on global climate changes as well as on the impacts of mining, agriculture and livestock.

The area surrounding the Zalama peat bog, in the Basque-Cantabrian Mountains (northern Iberian Peninsula) is also of biogeographical interest because it acts as the border between the Eurosiberian and Mediterranean regions. The existence of several mountain barriers parallel to the coastline limits the progressive arrival of Atlantic moisture, favouring complex and rich floristic variability (Aseginolaza et al. 1996). Therefore, this mountain region currently has a rich variety of landscapes, where floristic elements typical of the moist conditions of the Atlantic area coexist with species better adapted to the continental climate on the northern Spanish plateau. It is also a relatively unknown region from the palaeoenvironmental standpoint owing to the scarcity of palaeobotanical studies (Iriarte 2008; Pérez-Díaz et al. 2015). The only palynological research conducted in the area to date was carried out in the nearby peat bog of Los Tornos (Peñalba 1989, 1994; Muñoz-Sobrino et al. 2005). Some archaeobotanical studies (pollen, charcoal, seeds) have also been carried out at archaeological sites located in the bottom of the valleys, such as El Mirón (Iriarte 2012; Peña-Chocarro 2012; Zapata 2012), Cotobasero (Zapata 2002), La Boheriza (Iriarte 1995) and La Cabaña (Iriarte 1999). In short, all these factors, i.e. its nature as an ombrotrophic bog, its geographical location and the scarcity of palaeobotanical research in this area, make the Zalama peat bog extremely valuable for evaluating the landscape, climate conditions and human pressure during the Holocene.

In this paper, we discuss the Holocene evolution of the vegetation in the Basque-Cantabrian region over the last 8000 years. For this, we present a high-resolu-
tion study of pollen grains, spores and non-pollen palynomorphs, as well as geochemical data of trace elements from the ombrotrophic bog of Zalama (Basque-Cantabrian Mountains, northern Iberian Peninsula), this being probably the most southwesterly recorded example of a blanket bog in Europe (Heras & Infante 2005).

Study area

The study site is the peat bog of Zalama (latitude 43°8′6″N, longitude 3°24′35″W, altitude 1330 m a.s.l.), located in the vicinity of a peak of the same name, in the southwestermost corner of the Basque-Cantabrian Mountains (Ordunite Mountains, Basque Country, northern Iberian Peninsula). It is located on a gentle, domed hill on the watershed between the Cantabrian and Mediterranean hydrographic areas (Fig. 1A). This blanket bog is located near the main summit and is unaffected by water movement in streams or overland flow. The peat rests directly on periglacial deposits with quartzite fragments and therefore there is no other organic soil horizon (Fig. 1B; Heras & Infante 2004). Originally covering an area of 5 ha, it has been badly affected by fires used by cattle breeders to control pastures (Heras & Infante 2005). Today the burnt area is occupied by bare rock and mineral soil. The blanket bog still covers 2.5 ha (Heras & Infante 2004), and today is the subject of a major restoration project (Aguirre-Pascual 2011). The predominant geological bedrock is made up of Lower and Upper Cretaceous sedimentary rocks (Middle and Upper Albian–Lower Cenomanian) and sandstones with abundant quartz grains (Garrote et al. 1992).

The peat bog is located in an Atlantic climatic area. The nearest weather station (Cerroja) is located 10 km to the north. In 2014 the measurements indicated an average yearly precipitation of 1341 mm for a total of 185 rainy days, and a mean annual temperature of 13.7 °C (Euskalmet 2011). However, this station is located at a much lower elevation (677 m a.s.l.); at higher elevations rainfall is presumably heavier. It is also important to note that mist is frequently present on the nearby peaks even in summer, owing to the orographic barrier of the Basque-Cantabrian Mountains to the moist air from the Bay of Biscay. This constant moisture throughout the year is essential for the good preservation of the peat bog.

The current vegetation of the peat bog is composed of a dense peaty moorland of purely ombrotrophic characteristics, dominated by Calluna vulgaris, with Erica tetralix, E. cinerea, Molinia caerulea, Daboecia cantabrica, Sphagnum rubellum, Juncus squarrosum, Ulex gallii and Eriophorum vaginatum (Uribe-Etxebarria et al. 2006). There are also communities of Pteridium aquilinum, a heliophilous fern that sometimes grows on bogs (Fig. 1C). In the vicinity, the current forests are restricted to lower elevations (Bariego & Gastón 2002), with acidophilous beech forests composed of Fagus sylvatica, Ilex aquifolium, Vaccinium myrtillus, Deschampsia flexuosa, Blechnum spicant, Veronica officinalis and Euphorbia dulcis on the northern slopes. The southern slopes, where the insolation is greater, have Quercus pyrenaica forests with Pseudoar-rhenatherum longifolium, Pteridium aquilinum, Are-naria montana and Potentilla erecta, as well as scattered Scots pine (Pinus sylvestris) stands on the sunny slopes (Asegínolaza et al. 1996).

Material and methods

Coring and sampling

The core was taken using a Wardenaar corer (10×10×100 cm; Wardenaar 1987) for the first 100 cm and a Russian peat sampler (GYK type, 50 cm length; 5 cm in diameter) for the rest. The coring point was located in the centre of the peat bog, from where a core with a total length of 232 cm was extracted (Table 1). Contiguous sampling was performed in the uppermost 30 cm, where samples were taken every centimetre. The rest of the core samples were taken every 2 cm. Two surface samples were also taken at the peat–vegetation interface. A total of 131 samples was analysed.

Chronology

Selected peat samples were sent to Angström Laboratory of Uppsala University (Sweden) and Centro Nacional de Aceleradores of Sevilla University (Spain) for radiocarbon dating, in order to establish patterns of bog development. Chronology was based on 17 accelerator mass spectrometry (AMS) radiocarbon dates on peat material (Table 2). The dates were calibrated using the CALIB 7.1 radiocarbon calibration program with the IntCal13 curve (Reimer et al. 2013). An age/depth model (Fig. 2) was produced using CLAM 2.2 software (Blauw 2010), applying a smooth spline solution. Confidence intervals of the calibrations and the age/depth model were calculated at 95% (2σ) with 1000 iterations. The calendar scale was cal. a BP.

Pollen and NPP analyses

A total of 131 samples (each 1 cm³ in volume) was used for the palynological study. All of the palynological samples were chemically treated following Girard & Renault-Miskovsky (1969), with the samples being concentrated in a high-density Thoulet solution (Goe-ury & de Beaulieu 1979). Small aliquots of the residues were mounted in glycerine jelly, sealed with Histolacque. Pollen and spores were identified according to Feigri & Iversen (1989), Moore et al. (1991) and Reille (1999). Non-pollen palynomorphs were identified according
van Geel (1978, 2001, 2006); van Geel et al. (1981, 1989, 2003) and Cugny (2011). In each sample a minimum of 500 terrestrial pollen grains was counted. Cyperaceae, aquatics and spores were excluded from the pollen sum to avoid over-representation (Wright & Patten 1963). A pollen diagram (Fig. 3) was produced using the TILIA 2.0 and TGVIEW programs (Grimm 1992, 2004). Local pollen assemblage zones (LPAZs) were constructed on the basis of agglomerative constrained cluster analysis of incremental sum of squares (CONISS) with square-root-transformed percentage data (Grimm 1987).

Elemental geochemistry

Mineral contributions to bogs can be assessed using reference lithogenic elements present in rocks and soils. It can be assumed that variations in the trace elements in the ombrotrophic peat profile reasonably reflect fluctuations in the deposition of atmospheric soil dust (ASD) (Shotyk 1996; Pontevedra-Pombal et al. 2013). Titanium (Ti) and vanadium (V) are such elements. The total content of these elements was determined in the peat as a proxy of soil erosion. We performed a statistical normalization of the element content (Z-scores,
calculated by dividing the difference between the element content of each sample and the average value of the whole core by the standard deviation), which minimizes differences due to local effects (i.e. due to differences in the geological composition) and results in a relative scale of variation in enrichment to identify periods of elevated values.

In Teflon vessels an aliquot of 0.300 g of each sample was digested (180 °C – 5–1000 W and 180 °C – 10–1000 W) by microwave (Milestone, Ethos1 plus) using a mixture of 8 mL 69% HNO3 (PlasmaPURE-Scp Science) and 2 mL of 48% HF (Sigma Aldrich). Due to the high organic matter content, the addition of H2O2 was also required. Then, the digested sample was flushed in a final volume of 25 mL with 2.5% H3BO3 (Sigma Aldrich). The sample was filtered and stored in plastic tubes in the cold and dark until analysed by quadrupole inductively coupled plasma-mass emission spectrometry (ICP-MS) using a Varian 820-MS. Ten per cent of the samples were analysed in duplicate. All calibration standards were prepared as samples from multi-element solutions. For both elements, the correlation coefficients of the calibration lines were equal to or greater than 0.999. All measured elements were above the detection limits, whereas the blank sample values were below. To assess the precision and accuracy of analytical procedures and to check the calibration, we used five internationally certified reference materials (CRMs). Element recoveries

in CRMs were consistent with the certified values (Table 3). CRMs and blanks were inserted into every sample batch.

Results

Pollen zonation

The pollen diagram was divided into two main LPAZs (Fig. 3) using CONISS. The subzone ZAL-1 was in turn divided into three subzones (ZAL-1a, ZAL-1b and ZAL-1c). The diagram provides insight into the vegetation history of the Basque-Cantabrian Mountains from 8000 cal. a BP to the present, both at the local and regional scale.

Zone ZAL-1a (231–166 cm depth, 7975–6463 cal. a BP). – The oldest section of this LPAZ (231–208 cm, 7975–7585 cal. a BP) shows that the main arboreal taxon was Pinus (44–54%). Other taxa such as deciduous Quercus and Corylus have a secondary role (<20%). Juglans is present with values <5%. Shrubs reached noteworthy values, mainly Erica and Calluna. Poaceae registered the lowest values in the entire sequence (<10%). Hygrophilous taxa reached 5–8% of the total pollen. The rest of this LPAZ (208–166 cm, 7585–6463 cal. a BP) was characterized by the decline of pines, which decreased to 22%. Deciduous Quercus and Corylus percentages rose to 27 and 19%, respectively. Both shrubs (Erica and Calluna) and hygrophilous taxa (Poaceae, monolete and trilete ferns) were substantially represented.

Zone ZAL-1b (166–106 cm, 6463–4789 cal. a BP). – This LPAZ showed lower values for tree pollen (<65%), with mesophilous taxa as the main components. Deciduous Quercus exceeded 26%, with Corylus in a secondary position (maximum values of 18%). Pinus decreased (13–18%) and Juglans reappeared. Taxus appeared at this LPAZ with very low values. Shrub percentages declined, with Erica and Calluna as the main taxa. Herbs increased markedly (maximum values of 32%), with Poaceae as the main taxon (22%). This area is also characterized by higher percentages of Cardueae, Chenopodiaceae, Dipsacus fullonum, Plantago major/media, P. lanceolata and Urtica dioica, but with low values (<2%). Sordaria reached maximum values of 2%. Hygrophilous taxa showed lower values, almost all Cyperaceae.

Zone ZAL-1c (106–50 cm, 4789–2251 cal. a BP). – This zone had increasing values of tree pollen, reaching 68%, the main contributor being Corylus (27%). Other mesophilous taxa that maintained a continuous and significant presence were deciduous Quercus (16–25%). In this LPAZ, Fagus occurred for the first time in the succession, at 3900 cal. a BP. Pine-pollen percentages exhibited a decreasing trend. Amongst the shrubs, Erica and Calluna were best represented. Herbs displayed a significant presence (21–31%), with Poaceae as the main taxon (maximum 25%). Cichorioideae and Fabaceae also displayed an increasing trend. From 4000 cal. a BP, Cyperaceae and monolete and trilete ferns showed an increasing trend. Amongst non-pollen palynomorphs, Sordaria reached a maximum peak of 5.2% at 3460 cal. a BP.

registering values of <3%. Hygrophilous taxa increased their values. The main non-pollen palynomorph was Sordaria (4.5%).

Geochemical record

The mean, standard deviation, and maximum and minimum concentrations of Ti and V and ash content are summarized in Table 4. The values found were comparable to those found in bogs throughout Europe (Shotyk et al. 2002; Coggins et al. 2006; Cloy et al. 2011; Allan et al. 2013; Pontevedra-Pombal et al. 2013). Ti and V concentrations were significantly correlated ($r = 0.948; p < 0.0001; N = 129$), and both closely followed the ash content ($r = 0.837$ and 0.828 respectively; $p < 0.001; N = 129$), suggesting that the inorganic content of the peats was supplied by atmospheric soil dust. The ash content and concentrations of lithogenic elements (Ti and V) showed a similar trend (Fig. 4) during bog development. Background values were not exceeded until after 4000 cal. a BP. From then on, the three geoindicators gradually increased until the present. The greater increase detected in the last 500 years is attributable to greater soil erosion resulting from agricultural and industrial intensification or to climatic changes over the last millennium (Le Roux et al. 2004; Zaccone et al. 2008; Pontevedra-Pombal et al. 2012).

Discussion

Pines vs. deciduous forests in the Basque-Cantabrian Mountains (8000–6500 cal. a BP)

The oldest part of the Zalama pollen record shows the highest values of pine pollen of the entire succession, reaching a maximum of 44% (Fig. 3). These values are not sufficient to support the presence of large pine forests in the local environment of the site. It is known that most pines, due to high pollen production and good dispersal ability, have a larger pollen-dispersal area than do other tree species (Poska & Pidek 2010). According to studies of modern pollen rain in some well-developed pine forests, composed mainly of Pinus sylvestris, we infer the presence of large pine forests only when the values reach 60% (López-Sáez et al. 2013). Accordingly, we suggest at this time the presence of regional pine forests, or perhaps the presence of scattered trees near the site, but in any case mature forests. The significance of our data is that they indicate the presence of pine forests in the study area during the middle Holocene, although these forests do not have a phytosociological characterization in the literature of northern Spain (Rivas-Martínez 1987). One compelling question is what species of pines were present in the environment in the last eight millennia. Although we could not distinguish between them and we retrieved no macro-remains, we suggest that the vast majority of pine pollen in the core originated from Pinus sylvestris because it is the only species remaining today in the area surrounding the peat bog (Aseginolaza et al. 1996). In this area, the 19th-century authors Willkomm & Lange (1861), following the works of Planelles (1852) and Olazabal (1856), suggested the nature of relict Scots pine forests in the Cantabrian Mountains (Rubiales et al. 2010, 2012). Similarly, Catón-Santaren & Uribe-Etxebarria (1980), Ruiz-Urrestarazu (1989) and Aseginolaza et al. (1996) pointed to the presence of relict Pinus sylvestris forests in the Basque Country, hardly altered by anthropogenic activities in the last millennium. However, we cannot completely rule out the contribution of other pines, such as Pinus nigra, macrofossils of which have been found in several deposits of the northern plateau (García-Amorena et al. 2011).

According to the data from the Zalama peat bog, from 7585 cal. a BP, pines suffered a major setback parallel to the development of deciduous forests in the Basque-Cantabrian Mountains. The reasons for this phenomenon are probably climatic. The increased precipitation and temperature in the early middle Holocene, as detected in lake, bog, marine sediment and speleothem records in the northern Iberian Peninsula (Santos et al. 2000; Roucoux et al. 2001; Moreno et al. 2011; Stoll et al. 2013), which resulted in tree recolonization, caused an early decline of pine forests across
the northern Iberian Peninsula. This phenomenon was sharper and more sudden in the Atlantic areas of northern Iberia, as demonstrated by Muñoz-Sobrino (2001), Muñoz-Sobrino et al. (2007) and Rubiales et al. (2008, 2011, 2012). Deciduous taxa, especially Quercus, Corylus and sometimes Betula, in this temperate and humid climate had certain advantages that allowed them to compete successfully against coniferous formations, which survived in other areas. Pines therefore remained in such regions as the more continental, dry inland areas of the southern slopes of the Cantabrian Range, less suitable for the competition of hardwoods (Muñoz-Sobrino 2001; Rubiales et al. 2008, 2011; Jalut et al. 2010; Muñoz-Sobrino et al. 2012). From these times, c. 7585 cal. a BP, deciduous trees formed the dominant forests in the environs of the Zalama bog. Above all, hazel and deciduous Quercus started to play a major role in local forests. Deciduous Quercus had already gained terrain since the decline of pines, and became one of the dominant Holocene forest taxa. Hazel was also a foremost species in the wet mesophylous forest of the northern Iberian Peninsula, where it formed part of mixed deciduous formations.

Notably, Juglans also expanded its presence at this time. It was documented at the beginning of the sequence (ZAL-1), but between 6460 and 5500 cal. a BP (lower part of ZAL-1b) it became more abundant, although still with low values (<2%). Walnut has usually been considered to have been introduced into Western Europe during the late Holocene (Beug 1975), but research in the last few decades has provided sufficient data to demonstrate its indigenous nature in the Iberian Peninsula (Sánchez-Goni 1988; Carrión & Sánchez 1992; Ramil-Rego et al. 2000; Da Silva-Oliveira 2012; Mercuri et al. 2013), as in the case of the Zalama pollen record. In addition, some development of riparian communities (Alnus, Fraxinus and Salix) can be detected in the diagram, probably at a regional scale. This, together with the increase in fern spores (monolete and trilete) and Ranunculaceae, confirms the onset of more humid conditions in this period. This pattern is not an isolated event but a regional trend, involving the entire Atlantic area of northern Spain, as has been demonstrated in other deposits, such as the Los Tornos (Penalba 1989) and Pozo do Carballal (Muñoz-Sobrino et al. 1997) peat-bog pollen records. A multi-proxy climatic reconstruction for Enol Lake suggests favourable temperatures and the presence of highly stable forested landscapes at 8700–4650 cal a BP (Moreno et al. 2011).

**First anthropogenic evidence (c. 6500–3300 cal. a BP)**

In addition to the regression of pines and the progressive advance of deciduous forests, other changes in the landscape were detected by 6500 cal. a BP in the Zalama pollen record. The most notable are related to the first evidence of human impact c. 6460 cal. a BP. From then on, the pollen diagram reflects some decrease in forests and their replacement by open areas, mainly pastures of Poaceae and other synanthropic taxa (Plantago lanceolata, P. major/medium, Urtica dioica, Caryophyllaceae, Chenopodiaceae and Cichorioidae; Fig. 3). These elements, together with the contemporaneous appearance of coprophilous fungi (Sordaria), suggest nearby pastures and pastoral pressure (Behre 1981; Sjögren 2006; López-Sáez & López-Merino 2007; Sjögren & Lamentowicz 2008). In addition, the presence of pyrophilous taxa (Asphodelus albus) and carbonicolous fungi (Chaetomium sp.) appears to reflect the use of fire as a tool for opening spaces by early farming communities (van Geel 1978; Kuhry 1985).

These first pieces of evidence of human impact on forests are related to early cattle raising in the Basque-Cantabrian Mountains. The northern area of the Iberian Peninsula in general and the Basque-Cantabrian Mountains in particular, have been considered marginal areas for Neolithic farming (Zapata & Pena-Chocarro 2013). However, in the last decade several archaeological findings, supported mainly by archaeobotanical research, have refuted these assumptions (Zapata 2002; Zapata et al. 2004). In fact, such evidence can be explained by the profusion in the region of archaeological sites precisely dated to the Early Neolithic (end of the 8th and first half of 7th millennia ago) such as Los Canes, Los Gitanos, El Miron, Kobaederra, Pico Ramos, Lumentxa, Arenaza, Herriko Barra and Marizulo (Zapata et al. 1997, 2007; Alday & Mujika 1999; Arias & Altuna 1999; Zapata 2002; Iriarte et al. 2004; Arias 2005; Pena-Chocarro et al. 2005; Ontañón et al. 2013). This phenomenon of increased human impact is also detected in the pollen records of the nearby Monte Areo (López-Merino et al. 2010) and Pena Veira peat bogs (Ramil-Rego & Aima 1993). This intensity of human impact (forest clearance and burning) 6500 years ago has also been recorded in other regions of northern Spain such as Galicia, by clear signs of erosion, cumulic soil formation and the appearance of stone and charcoal lines (Kaal et al. 2008).

This anthropogenic evidence indicates some reduction in human activity in the Zalama peat bog between 4800 and 3400 cal. a BP, this being manifested in the interruption of continuous curves of different taxa such as Sordaria, Urtica dioica, Plantago lanceolata, Dipsacus fullonum, Cichorioidae, Chenopodiaceae and Aster (Fig. 3). This phase of less human pressure during the Copper and Early Bronze Ages is also reflected by the expansion of hazel, which prospered because of its pioneering nature (Costa-Tenorio et al. 2005), and occupied certain areas previously devoted to pasture. This episode is part of a long-term climatic
phase of global cooling (Magny & Haas 2004), which has also been recorded in the northwestern Iberian Peninsula (Fábregas et al. 2003).

Another noteworthy phenomenon during this time is the beginning of the continuous curve of *Taxus*. This plant was not identified previously, but c. 6000 cal. a BP it makes its appearance in the Zalama pollen record with a continuous curve until 3000 cal. a BP. Its presence is not prominent (<2%) but its appearance at this time is remarkable.

Although it is an anemophilous tree, its pollen production and dispersal rate are very low. Some studies show a meagre representation in surface samples taken near the tree, reflecting that even extremely low pollen values (1–2%) must attest to the local presence of this genus (Heim 1970; Noryskiewicz 2003). The increase in the use of yew wood is detected at some archaeological sites located in northern Iberia dated to the Early Neolithic, such as El Mirón, Aizpea and other archaeological sites in the Sierra de Cantabria (Zapata 2001, 2012; Ruiz-Alonso 2014). However, from the charcoal record alone it is difficult to determine the real significance of *Taxus* in the landscape. Indeed previous studies have shown that wood macro-remains linked to human settlements can be used only as indicators of the presence of this genus (Heim 1970; Noryskiewicz 2003). From 6000 cal. a BP the first continuous curves of yew pollen are recorded in many deposits located in the northern Iberian Peninsula, particularly in some well-dated peat bogs such as Zalama and the nearby Los Tornos in the Basque-Cantabrian Mountains as well as in other pre-Pyrenean bogs such as Atxuri and Belate (Peñalba 1989; Pérez-Díaz et al. 2015). They all have continuous pollen values spanning a quite similar chronology, between 6000 and 2700 cal. a BP. In another pollen record, Saldropo (Peñalba 1989, 1994), no continuous values were recorded, but rather only isolated occurrences 5000–2750 cal. a BP.

In this last phase, the forests in this area underwent a major change, a transformation led by the expansion of a single taxon: *Fagus*. Its first appearance in the Zalama pollen record was dated to 3900 cal. a BP with sporadic, discontinuous and low values. However, from 3300 cal. a BP the pollen diagram shows the presence of a continuous curve of this new element, and from 3000 cal. a BP its values exceed 1%, reaching a maximum of 13% (Fig. 3). Therefore, beech forests were one of the main vegetation communities in the late Holocene of the Basque-Cantabrian Mountains and nearby regions such as the western Pyrenees and Cantabrian Region (Table 5).

It is currently accepted that the present Iberian beech forests originated from populations located in several refuge areas, according to the growing number of palaeobotanical finds in ancient chronologies and genetic studies (Martínez-Atienza & Morla-Juaristi

**Fig. 5.** Distribution of Ti and V trace elements over time and the main changes in the vegetal landscape in the late Holocene record of Zalama peat bog.

Regarding the prevailing climate conditions in this area, the palynological record of Zalama indicate some increase in effective moisture by the rising values of Corylus and fern spores since 3300 cal. a BP. Similarly, other regional studies, such as the multi-proxy analysis of the Enol Lake mentioned above, suggest a wetter climate with more humid conditions between 4650 and 2200 cal. a BP (Moreno et al. 2011). Such conditions would be optimal for Fagus development.

The other agent perhaps involved in this process, human disturbance, caused open landscapes as a result of agropastoral activities, which could have favoured Fagus regeneration (Iversen 1973; Watts 1973; Björkman 1999). This would have allowed them to form mixed forests with other deciduous tree formations, and later monospecific beech forests.

In the succession of Zalama, from 3400 cal. a BP (Middle Bronze Age), the pollen diagram shows renewed anthropization, after a certain abandonment phase mentioned above (4800–3400 cal. a BP). This is manifested by some intensification in local pastoral activities and some indicators of disturbance associated with fire and overgrazing (Chaetomium sp. and Asphodelus albus). This phase coincides with lithogenic elements surpassing, for the first time in the Zalama record, their background levels, as represented by their z-scores (Fig. 5), indicating greater soil erosion. Passing this first buffering threshold may be an indirect sign of the aforementioned deforestation, but also of the intensity of the direct impact of the increased use of soil resources, coinciding with the more abundant cereal pollen and coprophilous fungi spores (Fig. 3). The beginning of these erosive crises has been detected in soils, peatlands and archaeological sites around the northwestern Iberian Peninsula (Fábregas et al. 2003). In the Zalama bog, the ash content and V and Ti concentrations began to increase before any remarkable sign of forest decline. This characteristic has also been detected in other studies, suggesting that lithogenic geoindicators are more sensitive to small changes in the landscape than pollen is (Hölzer & Hölzer 1998; Martínez-Cortizas et al. 2005). This phenomenon of increasing anthropization by 3400 cal. a BP occurred at the same time as the start of the continuous curve of Fagus (Fig. 3). Thus it seems probable that the expansion of beech was favoured by anthropogenic disturbances, as seen in other parts of Europe such as the French Pyrenees (Galop & Jalut 1994; Jalut et al. 1998) or even within the Iberian Peninsula (Ramil-Rego et al. 2000; Martínez-Cortizas et al. 2005; López-Merino et al. 2008). The emergence of beech in the vegetation of the Basque-Cantabrian Mountains significantly affected the existing forest communities. The mixed deciduous forests dominated by Quercus and Corylus suffered a significant setback at this time because of the great competitive ability of beech in disturbed environments.

The emergence of Fagus coincides also with the decline of Taxus c. 3000–2700 cal. a BP. This decline does not appear to be due to a single factor but rather to the co-occurrence of different elements, both natural and human, which encouraged these regressive dynamics in the late Holocene. Amongst the major causes, several biological, environmental and anthropic factors can be noted: e.g. increasing anthropic pressure, competition with other tree species (mostly Fagus) and self-regeneration problems (Izsikulo 2010; Linares 2013). Other taxa harmed by the expansion of beech were the conifers. Pines, which displayed a regressive trend throughout the Holocene (García-Antón et al. 1997), also suffered a significant setback at that time, and almost disappeared from the pollen record of the Zalama peat bog (Fig. 3).

In addition to the beech forest formations, other elements now played a major role at a local scale, i.e. shrubs. From 2250 cal. a BP these thickets showed an increasing trend, with a greater representation of Calluna vulgaris and Erica. This coincidence with other notable evidence of human impact (some deforestation, anthropogenic taxa and grasslands) may indicate that this expansion of shrubs must be originated by the perturbations derived from the extension of grazing areas related to the expanding use of this pastoral setting. In the Zalama bog, this phase of retreat in trees, expansion of Fagus and shrubs, and in general, anthropization of the landscape is synchronous with a dramatic increase in ASD deposition (Fig. 5), which marks the beginning of intensifying soil erosion. Besides consistency with biotic markers of agriculture and grazing, this erosive phase was also coeval with the onset of iron metallurgy in the Cantabrian-Pyrenean area, the development of which led to extensive deforestation (Etxezarreta 2004). The same erosive phase was recorded in polycyclic soils and peatlands in northwest Iberia, including by dense lines of charcoal, gravel and stones, and growing palaeopollution (van Mourik 1986; Martínez-Cortizas et al. 2005; Costa-Casais et al. 2009; Pontevedra-Pombal et al. 2013; Silva-Sánchez et al. 2014). These shrublands have dominated the landscape at a local scale until the present in our study area. The main components of the landscape near the bog are currently Calluna vulgaris
and 	extit{Erica tetralix}. This phenomenon of heathland expansion is commonplace in the northwestern Iberian Peninsula for this period (e.g. Allen et al. 1996; Muñoz-Sobrino et al. 1997; Muñoz-Sobrino 2001; Morales-Molino et al. 2011, 2013; Morales-Molino & García-Antón 2014).

Conclusions

The study of the raised ombrotrophic bog of Zalama contributes to the knowledge of the evolution of the landscape in the northern Iberian Peninsula during the Holocene. The bog’s location on the border between the Eurosiberian and Mediterranean regions offers an added value, reflecting the history of vegetation dynamics, climatic conditions and anthropogenic activities in a region of special biogeographical interest.

The beginning of the succession (8000 cal. a BP) is characterized by pine forests, showing the importance of pine woods in the southwestern European landscape in the early middle Holocene. The climatic conditions, more humid and temperate, triggered the retreat of 	extit{Pinus sylvestris} from this area, dated in Zalama from 7600 cal. a BP. In this context, rising temperatures and greater precipitation favoured the development of deciduous forest (oak, hazel, birch), much better adapted to the new conditions. Since then, pines have been restricted to the more continental and drier areas on the southern slopes of the area.

Palaeobotanical data show that yew has been present in several places in the northern Iberian Peninsula since at least the Pleistocene. However, higher values are documented during the middle Holocene. From 8000 cal. a BP, significant use of yew wood appears in archaeological contexts. From 6000 cal. a BP, yew expands somewhat, according to its increasing presence in the pollen records. This phase lasted several millennia, until the late Holocene, when yew populations underwent a regression around 3000 cal. a BP.

The first anthropogenic disturbances are noted in the area of the Zalama peat bog during the middle Holocene. From 6400 cal. a BP, pasturelands increasingly occupy some open areas in this mountain range. The presence of anthropogenic taxa and coprophilous fungi points to the new productive economic activities related to the first crop raising and animal husbandry in the Basque-Cantabrian Mountains.

In the late Holocene the biggest change in the vegetal landscape was the expansion of beech forests. The spread of beech forests in Zalama is documented from 3300 cal. a BP, at a very similar time as in other areas of the northern Iberian Peninsula. Anthropogenic perturbations may have favoured this phenomenon.

The geochemical record of the Zalama bog suggests that the carrying capacity of the soil was definitely exceeded in the late Holocene, beginning a sequence of erosive phases contemporaneous with deforestation and the expansion of anthropic spaces and widespread shrublands.
