Abstract

We study, in this paper, a taxi-sharing problem, called Dial-a-ride problem with money as an incentive (DARP-M). This problem consists in defining a set of taxis that will be shared by different clients in order to reduce their bill by a given factor $\alpha < 1$. To achieve this, each client shares the cost of the ride with other passengers. More precisely, the fragments of the ride in which the client is alone is fully paid by this client and, for each fragment in which the client shares the taxi with other passengers, the cost is equally divided between the passengers. In addition to this cost constraint, the taxi must satisfy a time window constraint for each passenger and a capacity constraint.

We define three versions of the problem: max-DARP-M where the objective is to drive the maximum number of clients with an arbitrarily large number of taxis; max-1-DARP-M in which we want to drive the maximum number of clients with one taxi; and 1-DARP-M which consists in deciding whether it is possible to drive at least one client while satisfying the constraints. We study the parameterized complexity and approximability of those problems with respect to four parameters: the factor $\alpha$, the capacity $\text{capa}$ of the taxis, the maximum size $W$ of the time windows of the clients, and the value $S$ of an optimal solution.

Among other results, we prove that 1-DARP-M is NP-Complete and max-DARP-M and max-1-DARP-M cannot be approximated in polynomial time to within any variable ratio even if $\alpha$, $\text{capa}$ and $W$ are fixed and if the road network is a planar graph. We also give a polynomial algorithm for max-1-DARP-M for the case where $\text{capa}$ and $W$ are fixed and where the network does not contain a circuit. This algorithm implies a $\frac{1}{\sqrt{n}}$-polynomial approximation for max-DARP-M.

Keywords: Parameterized complexity, Approximability, Dial-a-ride problem, Taxi-Sharing
1. Introduction

The Dial-a-Ride problem (DARP) consists in the search for an optimal route for many vehicles in order to drive people from their respective origin to their respective destination. This model is used, for example, to determine an optimized route for taxis in order to pick up passengers. We focus in this article on the complexity of a version of this taxi-sharing problem in which the price paid by each passenger is shared. Such a version, called Dial-a-ride problem with money as an incentive, was previously introduced and studied in [19, 20].

Ride-sharing, including Taxi-sharing, has been massively studied for the last fifteen years due to the economical impact and the ecological impact of such a research. Indeed, optimizations reducing the number of vehicles or the number of travels is an obvious way to reduce the costs and the greenhouse gas emissions. DARP can be seen as a subproblem of the general pickup and delivery problem (GPDP) described in [21] in which the goal is to transport a resource from different pickup locations to drop off locations. In DARP, we consider a human resource (the clients) and each pickup or drop off location is associated with exactly one client. The consequence of this specific resource is that one must be aware of the user inconvenience.

1.1. Related work on the DARP problem

DARP can hardly be defined as a unique problem. The feasible and optimal solutions of a Dial-a-ride problem depend on the measure, the fleet parameters and the clients constraints. Thus, the variety of studies about DARP is not surprising.

Considering the measure, one may optimize the vehicle travel cost, see for example [3, 15, 18], the total travel time [10] or the profit [7]. Another option is to maximize the number of satisfied requests or a combination of all those parameters [19, 20, 22].

Some constraints modelize the user convenience. A usual option is to search for a feasible solution considering time windows [4, 10, 18, 22] as it has been done for the more general pickup and delivery problem [8]. This last problem is solved with a column generation scheme where columns define admissible routes. In [10, 18], the authors develop a similar approach merging a branch-and-cut algorithm with column generation. In [4, 22], the problem is solved using a Tabu search heuristic. Another option to modelize the user convenience is to tend to minimize the excess ride time [2, 11, 13].

Finally one can consider either the static problem in which all the requests are known in advance or the dynamic version in which the requests may occur at any time [1, 6, 11, 19, 20], this problem is usually solved using a local search heuristic.

A recent review about the Dial-a-ride problem and some of its generalizations may be found in [14]. We refer the reader to [5, 10] for a more specific review about DARP.
1.2. DARP with Money as an incentive

We focus on a problem where the goal is to find a feasible solution satisfying a client cost constraint. Few papers focused on that constraint. In [19, 20], the authors study the version of the problem in which each client, traveling by taxi, may share the cost of the ride with other passengers. More precisely, the fragments of the ride in which the client is alone is fully paid by this client. On the contrary, for each fragment in which the client shares the taxi with other passengers, the cost is equally divided between the passengers. The problem consists in the search for a ride in which every client does not pay more than the cost he would pay alone in a taxi traveling directly from his origin to his destination. Note that a client can be served by being affected to a private ride but each client must also satisfy a time window constraint. The objective is to maximize the number of served clients. This problem is called Dial-a-Ride problem with Money as Incentive and is denoted by DARP-M.

In [20], the authors give a reduction from the Traveling salesman problem to DARP-M, based on the sole time windows constraint. However, no taxi is shared, all the clients are driven in a private ride. It proves that serving all the clients and satisfying a time windows constraint is NP-Complete. Considering this reduction, DARP-M can be seen as a generalization of TSP in which we add a sharing cost constraint. Although this reduction clearly shows that DARP-M is strongly NP-Complete, it does not reflect the hardness of determining if at least two clients can be served by sharing a taxi while satisfying the cost constraint. That simpler question is not insignificant as it leads to a natural greedy algorithm for DARP-M in which we group clients who can share a taxi until all of them have to be affected to a private rides.

Furthermore, it was shown by [17] that searching for a (not elementary) shortest path between a source and a sink satisfying a time windows constraint is weakly NP-Complete as it can be solved in polynomial time if the width of the time windows is polynomially bounded. Consequently, as the reduction of [20] uses only the time windows constraint and as it is from the strongly NP-Complete problem TSP, it seems that it cannot be easily adapted to prove the hardness of determining if at least two clients can share a taxi.

1.3. Our contributions

We focus on the parameterized complexity and the parameterized approximability of three problems derived from DARP-M defined by [19, 20]. The purpose of this paper is mainly to investigate on how hard the cost constraint is. Particularly, we point out the fact that every hardness result we give is true even if we do not take into account the time windows.

We now formally define the problems we study. We work in a directed graph $G = (V, A)$. We are given a set of $n$ clients arbitrarily numbered in $[1; n]$. The i-th client is attached to two nodes $v_i$ and $v'_i$, which are respectively the origin and the destination of the client. We respectively define $V_c$ and $V'_c$ as $\{v_i, i \leq n\}$ and $\{v'_i, i \leq n\}$. A route $P$ of a taxi is defined by a list $(u_1, u_2, \ldots, u_{2 \cdot s(P)})$ of nodes in $V_c \cup V'_c$ where $s(P)$ is an integer. A taxi must satisfy three constraints.
\textit{Precedence constraint.} For each client \(i, v_i \in P\) if and only if \(v_i' \in P\). In that case, if \(v_i = u_j\) and \(v_i' \in u_k\), then \(j < k\). We say the client \(i\) \textit{travels} in that taxi, or that the taxi \textit{drives} the client \(i\). The value of \(s(P)\) can be seen as the number of clients traveling in \(P\).

\textit{Capacity constraint.} We consider that each taxi has the same number of seats. This number is defined as the capacity \(\text{capa}\) of the taxis. This capacity is at least 2 and is no more than \(n\). For each node \(u_j \in P\), let \(n_j = \#\{u_k \in V_c, k \leq j\} - \#\{u_k \in V'_c, k \leq j\}\). This value is the number of clients in the taxi immediately after \(u_j\). For every \(j\), \(n_j \leq \text{capa}\). In addition, if \(j \neq 2 \cdot s(P)\), \(n_j \geq 1\): a taxi cannot be emptied before the end of the ride.

\textit{Time constraint.} Each arc \(a = (u, v) \in A\) is weighted with a non-negative integer \(t(a)\), corresponding to the time that a taxi spends to go from \(u\) to \(v\). We extend this function to every couple of nodes in \(G\): \(t(u, v)\) is the weight of a shortest path in \(G\) from \(u\) to \(v\). Each client \(i\) is associated with two moments \(b_i\) and \(e_i\). A taxi must drive that client between times \(b_i\) and \(e_i\). The taxi can start at any moment of the time window of its first client. We respectively define \(B_c\) and \(E_c\) as the sets containing all the values \(b_i\) and \(e_i\) for all the clients.

\textit{Cost constraint.} Each arc \(a = (u, v) \in A\) is weighted with a non-negative integer \(\omega(a)\), corresponding to the cost that a client would pay alone in a taxi driving from \(u\) to \(v\). We extend this function to every couple of nodes in \(G\): \(\omega(u, v)\) is the cost of a shortest path in \(G\) from \(u\) to \(v\). We define the \textit{desired gain} \(\alpha < 1\) as the minimum factor reducing the bill of each client. The cost paid is divided between the passengers traveling on the same arc: for each client \(i\) traveling in \(P\), if \(v_i = u_j\) and \(v_i' = u_k\), the cost paid by that client is

\[
\omega_i = \sum_{l=j}^{k-1} \frac{\omega(u_l, u_{l+1})}{n_j}.
\]

This cost must satisfy \(\omega_i \leq \alpha \cdot \omega(v_i, v_i')\). In that case, we say the taxi \(P\) \textit{satisfies} the client \(i\).

Note that there would not be any feasible solution if the capacity of the taxi is 1. This is why this case is forbidden.

\textbf{Remark 1.} A taxi \(P\) is only defined by waypoints in the road network: the origins where it picks up clients and the destinations where it delivers them. In order to draw the route of the taxi in the network, we follow the shortest paths in \(G\) from \(u_j\) to \(u_{j+1}\) for every \(j < 2 \cdot s(P)\). (We assume that a shortest path over the costs \(\omega\) is also a shortest path over the weights \(t\).) That route is a path of \(G\) that can contain intermediate nodes that are neither an origin nor a destination of a client driven by \(P\).

We can now define the problems max-DARP-M, max-1-DARP-M and 1-DARP-M.

\textbf{Definition 1.} Given a directed graph \(G = (V, A)\) with non-negative weights \(\omega\) over the arcs, \(n\) clients with their origin \(V_c\), their destinations \(V'_c\) and their time windows \(B_c\) and \(E_c\), a capacity \(\text{capa} \leq n\) of the taxis, a desired gain \(\alpha < 1\),

- the max-DARP-M problem consists in finding a set \(P\) of taxis satisfying the precedence constraint, the capacity constraint the time constraint and
the cost constraint maximizing $\sum_{P \in P} s(P)$ such that for each client there is a unique taxi of $P$ in which that client travels;

- the max-1-DARP-M problem consists in finding a taxi $P$ satisfying the four constraints and maximizing $s(P)$;
- the 1-DARP-M problem consists in deciding whether a taxi $P$ satisfying the four constraints exists.

We define also define two decision problems max-DARP-M and max-1-DARP-M in which, given an instance of max-DARP-M or max-1-DARP-M and an integer $S$, we search for a solution for which the objective value equals $S$. We finally define the parameter $W$ as $\max_{i \in [1:n]} (e_i - b_i) + 1$, the maximum width of a time window.

The results are summarized in Table 1.

Table 1: This table summarizes the set of results in the paper. The parameters column specifies which parameter is fixed or polynomially bounded. An hyphen in the approximability column means that the cell does not make sense, either because the problem is polynomial (or XP), or because the line is about a decision problem. The last column indicates in which theorem/corollary the result is proven.

</table>
Remark 2. We studied the problems in two main cases: planar and acyclic graphs. If the first may seem relevant considering the application, the second is clearly not as a road network hardly is acyclic. However, there exists parameterized algorithms for the three problems in that case. Its could be used if the circuits of the graph are removed (by defining a priority order over the nodes of the graph using, for example, the time windows of the clients). Of course, this restriction removes feasible solutions but according to Table 1, none of those feasible solutions may be build in polynomial or FPT time by any parameterized algorithm.

Remark 3. Note that, on every hardness result where $W$ is fixed, the reduction first consists in setting the durations $t$ to 0 and the time windows to $[0, 0]$, so that the time constraint is trivially satisfied and that $W = 1$. This means that the same hardness results occur even if we remove the time constraint.

2. Planar graphs

This section is dedicated to proving that 1-DARP-M is NP-Complete and that max-DARP-M and max-1-DARP-M are NP-Hard and cannot be approximated to within any constant or variable ratio, even if capa, $\alpha$ and $W$ are fixed and if the graph is planar.

In this proof, we fix capa = 2 and $\alpha \in ]0, 5[$. Note that it is possible to adapt the result for any fixed values of capa and $\alpha$. This adaptation is not trivial and make the proof harder to read. That is why we present in this section only the simple case. We also consider that we remove the time constraint by setting $t(a) = 0$ for every arc $a \in A$ and $b_i = e_i = 0$ for all $i$ and, in that case, $W = 1$.

Belonging to NP. We consider the decision version of max-1-DARP-M and max-DARP-M in which, given an instance of the optimization problems and an integer $K$, we search for a set of taxis or a unique taxi satisfying at least $K$ clients.

Those problems and 1-DARP-M belong to NP as, given a taxi, we can easily determine whether the capacity, the cost and the precedence constraints are satisfied for every client in the taxi and count how many clients are satisfied by the taxi.

NP-hardness: the reduction. In this part, we prove a reduction from the 3-partition problem to 1-DARP-M. We then deduce the hardness of approximation results for the optimization problems.

Given $n$ positive integers $X = [x_1, x_2, \ldots, x_n]$, with $n = 3m$, the 3-partition problem consists in the search for a partition $S_1 \cup S_2 \cup \cdots \cup S_m$ of $X$ such that $|S_j| = 3$ and $m \cdot \sum_{x \in S_j} x = \sum_{x \in X} x$ for all $j \leq m$. Let $B = \frac{1}{m} \sum_{x \in X} x$. The 3-partition problem is NP-Complete even if $x_i \in ]B/4; B/2]$ for each $i \leq n$ [9].

We define two real values $1 \leq \phi \leq \Omega$. We set those variables later in this proof. Let $n \geq 7$ be an integer and $X = [x_1, x_2, \ldots, x_n]$ be an instance of 3-partition such that $x_i \in ]B/4; B/2]$ for each $i \leq n$. We build an instance $J =$
\((G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha)\) of 1-DARP-M as follows. As it was previously said, we fix \(\text{capa} = 2\), \(\alpha \in [0.5, 1]\), \(t(a) = 0\) for every \(a\) and \(b_i = e_i = 0\) for every client \(i\).

There are 3 categories of clients:

- the main clients: \(m\) clients \(c_j\), for \(j \in \{1; m\}\), going from \(u_j\) to \(u'_j\);
- 2 clients \(a_1\) and \(a_m\), going respectively from \(v_1\) to \(v'_1\) and \(v_m\) to \(v'_m\).
- \(m \ast n\) clients \(d_{ij}\), for \(i \in \{1; n\}\), \(j \in \{1; m\}\) going from \(w_{ij}\) to \(w'_{ij}\).

Figure 1 illustrates the graph \(G\) and the costs \(\omega\). Note that, for each client \(c_j\), the cost of a private ride is \(2\Omega\). For the clients \(a_1\) and \(a_m\), the cost is \(\Omega\). For the clients \(d_{ij}\) for \(j \neq 1\), the cost is \(\phi\) and for the clients \(d_{1i}\) the cost is \(\phi + x_i\).

Note also that the graph is planar.

Figure 1: A reduction from 3-partition to max-1-DARP-M. Note that this graph can be drawn planar if we move \(u_1\) and \(v_1\) above \(u_2\) and \(v'_1\) above \(u'_1\).
We set $\Omega$ and $\phi$ as follows:

\begin{align*}
\phi & \geq B + 1 \\
\Omega &= \frac{n\phi + B + \frac{1}{2}}{4\alpha - 2}
\end{align*}

We start by proving useful properties on $\phi$ and $\Omega$.

Lemma 2.1. $\Omega$ and $\phi$ satisfy the following properties:

\begin{align*}
2\Omega + n\phi + B + 1 & > 2\alpha \Omega \\
2\Omega + n\phi + B & \leq 2\alpha \Omega \\
\frac{3}{2}\Omega + \frac{n\phi}{2} & > 2\alpha \Omega \\
\frac{\Omega}{2} & > \alpha \cdot (\phi + B)
\end{align*}

Proof. Equation (2) proves that

\begin{align*}
\frac{n\phi + B}{4\alpha - 2} & \leq \Omega < \frac{n\phi + B + 1}{4\alpha - 2} \\
n\phi + B + 2\Omega & \leq 4\alpha \Omega < n\phi + B + 1 + 2\Omega
\end{align*}

and this proves Equations (3) and (4).

We now prove Equation (6). As $\alpha < 1$,

\begin{align*}
4\alpha(4\alpha - 2) & < 8 \text{ and } 2\alpha(4\alpha - 2) < 4
\end{align*}

We recall that $n \geq 7$ and $B > 0$,

\begin{align*}
0 & < (n + 1 - 4\alpha(4\alpha - 2))B + (n - 2\alpha(4\alpha - 2)) + \frac{1}{2} \\
0 & < (n - 2\alpha(4\alpha - 2))(B + 1) + (1 - 2\alpha(4\alpha - 2))B + \frac{1}{2}
\end{align*}

By Equation (1)

\begin{align*}
0 & < (n - 2\alpha(4\alpha - 2))\phi + (1 - 2\alpha(4\alpha - 2))B + \frac{1}{2} \\
2\alpha(4\alpha - 2)(\phi + B) & < n\phi + B + \frac{1}{2}
\end{align*}

By Equation (2)

\begin{align*}
\alpha \cdot (\phi + B) & < \frac{\Omega}{2}
\end{align*}
Finally, we can similarly prove Equation (5). As \( n \geq 7, \alpha < 1 \) and \( B > 0 \),
\[
0 < (n - (4\alpha - 3))(B + \frac{1}{2})
\]
By Equation (1)
\[
0 < n\phi + (3 - 4\alpha)(B + \frac{1}{2})
\]
\[
0 < (4\alpha - 2)n\phi + (3 - 4\alpha)(n\phi + B + \frac{1}{2})
\]
By Equation (2)
\[
0 < n\phi + (3 - 4\alpha)\Omega
\]
\[
2\alpha\Omega < \frac{n\phi}{2} + \frac{3}{2}\Omega
\]

NP-hardness: from \( X \) to \( J \).

Lemma 2.2. We now assume \( X \) is a YES-instance, then, \( J \) is a YES-instance.

Proof. Let \( I_1 \uplus I_2 \uplus \cdots \uplus I_m \) be a partition of \([1;n]\) such that \( \sum_{i \in I_j} x_i = B \) for all \( j \leq m \). The taxi picks up \( c_1 \) at \( u_1 \) and drives the client \( a_1 \) from \( v_1 \) to \( v'_1 \). Then, for \( j \in [1;m] \) it drives each client \( c_j \) from his origin to his destination such that, when the taxi drives \( c_j \) from position \( A \) to position \( B \), it drives the three clients \( d_i^j \) for \( i \in I_j \) and one client \( d_{k}^j \) for some \( k > 1 \) and every \( i \notin I_j \). Finally, while driving the client \( c_m \) from \( u_m \) to \( v'_m \), it picks up the client \( a_m \) at \( v_m \) and delivers them at \( v'_m \). In that case, the client \( c_j \) pays \( \frac{\Omega}{2} + \frac{n\phi + B}{2} + \frac{\Omega}{2} \). By Equation (4), the client \( c_j \) satisfies his cost constraint. Each other client pays exactly half of the price he would have pay alone. As \( \alpha > 0.5 \), it is a feasible solution for \( J \) satisfying every client.

NP-hardness: from \( J \) to \( X \). In order to prove the converse of Lemma 2.2, we first prove six intermediates results from Lemma 2.3 to 2.8.

Lemma 2.3. The three following cases are not possible:

- The taxi drives a client \( d_j^i \) to a node which is not \( w_j^i \).
- The taxi drives the client \( a_1 \) to a node which is not \( v_1' \).
- The taxi drives the client \( a_m \) to a node which is not \( v_m' \).
Proof. If the taxi drives the client $d_i^j$ to any node different from $w_i^j$, that client must go through at least one arc of cost $\Omega$ in order to reach his destination. By equation (6), even if there is another client in the taxi with $d_i^j$, he has to pay at least $\alpha \cdot (\phi + B)$. However, in a private drive, $d_i^j$ pays $\phi$ or $\phi + x_i$ depending on whether $j = 1$ or not. As $x_i \in ]\frac{B}{4}, \frac{B}{2}[\text{ for every } i$, $d_i^j$ cannot satisfy his cost constraint. A similar argument proves the two other cases.

**Lemma 2.4.** A feasible solution must start at $u_1$.

Proof. By enumerating every case, we prove that a taxi starting at any other position should pick up a client that could not satisfy the cost constraint.

1. If the taxi starts at $w_1$, the client $d_1^1$ must pay $\phi + x_1$ alone, and then cannot satisfy his cost constraint. Similarly the taxi cannot start at $w_j$ for any $j > 1$.

2. If the taxi starts at $v_1$, the client $a_1$ must pay $\Omega$ alone, and then cannot satisfy his cost constraint. Similarly, the taxi cannot start at $v_m$.

3. If the taxi starts at $u_i$, for any $i \geq 2$, the client $c_i$ must firstly pay at least $\Omega$ to reach position $A$. Then he pays at least $\frac{n\phi + \Omega}{2}$ from $A$ to his destination. By Equation (5), he cannot satisfy his cost constraint.

**Lemma 2.5.** All the following cases are not possible :

1. the taxi drives through an arc $(u_i, u_i')$

2. the taxi drives $c_i$ to the node $u_j$, for $j \neq i + 1$

3. the taxi drives $c_i$ to the node $u_i'$ but does not deliver it

4. the taxi drives $c_i$ to the node $u_i'$ alone, for $i \neq m$

5. the taxi never picks up $a_1$ while driving $c_1$

6. the taxi never picks up $a_m$ while driving $c_m$

Proof. If the first statement is true, then, by Lemma 2.3, the taxi can drive only one client $c_j$ or two clients $c_j$ and $c_k$ through that arc. Because a client alone in the taxi would have to pay at least $2\Omega > 2\alpha \Omega$, he would not satisfy his cost constraint. Consequently, there are two clients $c_j$ and $c_k$. One of them is not $c_i$. Without loss of generality, we assume that $k \neq i$. That client would have then to pay at least $\Omega$ through the arc $(u_i, u_i')$, then to reach position $A$, then to pay at least $\frac{n\phi}{2}$ to reach position $B$ and, finally, to pay at least $\frac{\Omega \phi}{2}$ to reach $u_k'$. By Equation (5), he cannot satisfy his cost constraint.

If the taxi goes to $u_j$ with the client $c_i$, he pays at least $\frac{\Omega}{2} + \frac{n\phi}{2}$ to go to $u_j$ from $u_i$. In order to reach his destination, he has to pay at least twice $\frac{\Omega}{2}$, through the arc $(u_j, u_j'_{-1})$ and through the arc $(u_i+1, u_i')$. By Equation (5), he cannot satisfy his cost constraint, this proves that the case 2 is not possible.

The cases 3 to 6 can be similarly proven. □
Lemma 2.6. While driving the client $c_i$ from his origin to his destination, the taxi drives exactly $n$ clients $d_j^k$ from their respective origin to their respective destination.

Proof. By the first statement of Lemma 2.5, in order to reach $u_i'$, the client $c_i$ must go from position $A$ to position $B$. If the taxi reaches position $A$ with $c_i$, that client is alone. Indeed, by Lemma 2.3, clients $a_1, a_m$ and $d_j^k$ cannot be driven to position $A$, and if the taxi drives another client $c_j$ to position $A$ from $u_i$, this contradicts one of the four first statements of Lemma 2.5. If we assume that strictly less than $n$ clients $d_j^k$ are driven from their respective origin to their respective destination, $c_i$ pays at least $\phi + \left(\frac{n-1}{2}\right)^2$ in order to reach position $B$ from position $A$. As the taxi goes through at least one arc of cost $\Omega$ to reach position $A$ from $u_i$ and to reach $u_i'$ from position $B$, his ride costs at least $\Omega + \phi + \left(\frac{n-1}{2}\right)^2 + \frac{\Omega}{2}$. Note that the same occurs if more than $n$ such clients are driven.

By Equation (1)

$$\Omega + \phi + \left(\frac{n-1}{2}\right)^2 \geq \Omega + \left(\frac{2n\phi + B + 1}{2}\right)$$

By Equation (3)

$$\Omega + \phi + \left(\frac{n-1}{2}\right)^2 > 2\alpha\Omega$$

Consequently, the taxi must picks up and delivers exactly $n$ clients $d_j^k$ from position $A$ to position $B$.

Lemma 2.7. In a feasible solution for $\mathcal{J}$, every client is satisfied.

Proof. By Lemmas 2.4, 2.5, 2.6, if there is a feasible solution, the taxi must start at $u_1$ and drive each client $c_i$ from his origin to his destination, each one goes from position $A$ to position $B$ and then is driven with exactly $n$ clients $d_j^k$. As there are $m$ clients $c_i$ and $n \cdot m$ clients $d_j^k$, every client $d_j^k$ is satisfied. Finally, $a_1$ and $a_m$ must be picked up and delivered by Lemma 2.5.

Lemma 2.8. While driving $c_i$ from his origin to his destination, it must drive exactly three clients $d_{i_1}^1, d_{i_2}^1$ and $d_{i_3}^1$ such that $x_{i_1} + x_{i_2} + x_{i_3} \leq B$.

Proof. By Lemma 2.6, the set containing the clients $d_j^1$ is partitionned into $m$ subsets, one subset $S_j$ for each client $c_j$, each client of $S_j$ is driven with $c_j$.

Then the client $c_j$ pays at least $\frac{\Omega}{2} + \frac{\left(\sum_{i \in S_j} x_i\right)^2}{2}$. If $\sum_{i \in S_j} x_i \geq B + 1$, by Equation (3), the client $c_j$ cannot satisfy his cost constraint.

Moreover, if $|S_j| < 3$, as $n = 3m$, there is a client $c_k$ such that $|S_k| > 3$. As $x_i \in \left[\frac{B}{2}, \frac{B}{2}\right]$, $\sum_{i \in S_k} x_i \geq B + 1$ and $c_k$ cannot satisfy his cost constraint.
Lemma 2.9. We now assume $J$ is a YES-instance then $X$ is a YES-instance.

Proof. There exists a taxi satisfying at least one client. By Lemma 2.7, every client $c_i$ is satisfied by that taxi. By Lemma 2.8, such a solution proves the existence of a partition $S_1 \uplus S_2 \uplus \cdots \uplus S_m$ such that $\sum_{x \in S_j} x \leq B$. As $\sum_{x \in X} x = mB$, then $\sum_{x \in S_j} x = B$ for all $j$. Consequently, $X$ is a YES-instance. \hfill \Box

By Lemma 2.2 and 2.9, we can deduce the following theorem.

Theorem 2.1. 1-DARP-M is NP-Complete even if $G$ is planar and if $\alpha$, capa and $W$ are fixed.

Corollary 2.1. max-DARP-M and max-1-DARP-M are NP-Hard and, unless $P = NP$, cannot be approximated in polynomial time to within any variable ratio, even if $G$ is planar and if capa, $\alpha$ and $W$ are fixed.

Proof. If we assume there exists a polynomial $r$-approximation algorithm $A$ for max-DARP-M, where $r$ is a function from $\mathbb{N}$ to $\mathbb{Q}^+$ satisfying $0 < r(p) < 1$. Let $J$ be an instance of 1-DARP-M and max-DARP-M. If no client can be satisfied, the optimal solution of $J$ is 0. Thus $A$ returns a solution of value $r(|J|) \cdot 0 = 0$. If some client is satisfied, the optimal solution of $J$ is greater than 1 and $A$ returns a solution of value greater than $r(|J|) \cdot 1 > 0$. We can then decide in polynomial time whether at least one client can be satisfied or not. There is then a contradiction with Theorem 2.1. The same result occurs for max-1-DARP-M. \hfill \Box

3. Directed acyclic graph

In the previous section, we proved hardness results for all the DARP-M problems even if we strongly restrict the instance. The reduction from 3-partition produced an instance in which any taxi must satisfy all the clients by cycling in the graph, driving multiple time through the same roads. Consequently, we study, in this section, the directed acyclic graph case, in order to establish the influence of directed cycles on the complexity of DARP-M.

Obviously, such a case hardly ever occurs on real road networks and finding a polynomial time algorithm does not seem relevant. However, we can arbitrarily order the nodes of the graph. For example, each client $i$ is associated with a time window $[b_i, e_i]$; we can order the origins and the destinations of the clients using the values of $b_i$ for the origins and $e_i$ for the destination. For instance, the taxi could drive from the origin $v_i$ to the origin $v_j$ only if $b_i < b_j$.

In this section, we show some hardness results for the acyclic case, a parameterized algorithm for 1-DARP-M and max-1-DARP-M with respect to capa and $W$, and an parameterized $\frac{1}{\sqrt{n}}$-approximation algorithm for max-DARP-M in capa and $W$. 
3.1. Hardness results

3.1.1. Hardness of approximation for max-DARP-M

In this section, we prove a hardness of approximation result for max-DARP-M when \( G \) is a DAG and when the parameters \( \alpha, \text{capa} \) and \( W \) are fixed.

The reduction. We prove a reduction from the 3-Dimensional Matching problem (3DM). Given three finite disjoint sets \( X, Y \) and \( Z \), and a subset \( S \) of triplets of \( X \times Y \times Z \), (3DM) consists in the search for a maximum size subset \( M \) of \( S \) such that for every couple \( (m_1, m_2) \) of \( M \), \( m_1 \) and \( m_2 \) are disjoint. (3DM) is NP-Complete and APX-Complete. [12]

From an instance \( \mathcal{I} = (X,Y,Z,S) \) of (3DM), we now build an instance \( \mathcal{J} = (G, (V_e, V'_e, B_e, E_e), \omega, t, \text{capa}, \alpha) \) of max-DARP-M where \( \text{capa} \) and \( \alpha \) are fixed such that \( \mathcal{I} \) has a feasible solution of size \( K \) if and only if \( \mathcal{J} \) has a feasible solution with \( K \) taxis satisfying \( 7K \) clients. An example is given in Figure 2. We consider that we remove the time constraint by setting \( t(a) = 0 \) for every arc \( a \in A \) and \( b_i = e_i = 0 \) for all \( i \) and, in that case, \( W = 1 \).

For each set \( s = (x, y, z) \in S \), we define four clients \( c_s, c'_s, c''_s \) and \( c'''_s \) going respectively from \( v_x, v'_x, v''_x \) and \( v'''_x \) to \( v'_y, v''_y, v'''_y \) and \( v'''_y \). For each element \( x \) of \( X \) (respectively \( y \) of \( Y \) and \( z \) of \( Z \)), we add a client \( d_x \), (respectively \( d_y \) and \( d_z \)) going from \( w_x \) to \( w'_x \) (respectively \( w'_y \) to \( w'_y \) and \( w'_z \) to \( w'_z \)).

We add an arc \( (w_x, w'_x) \) of cost 1 for each \( x \in X \). We add similar arcs for each \( y \in Y \) and each \( z \in Z \). For each set \( s = (x, y, z) \in S \), we add four arcs \( (v_x, v'_x), (v''_s, v''_y), (v''_s, v''_z) \) and \( (v'''_s, v'''_y) \) of cost 0. We also add two arcs \( (v'_x, w_x) \) and \( (v''_x, v'''_y) \) of cost 0. We similarly link the nodes of \( c''_y \) and \( c'''_z \) to the origin and destination of \( d_y \) and \( d_z \).

Finally, we set \( \text{capa} = 3 \) and \( \alpha = \frac{1}{4} \). Consequently, there must be 3 clients in the taxi when it drives through an arc of cost non-zero.

Note that \( G \) is a DAG.

NP-Hardness.

**Theorem 3.1.** max-DARP-M is NP-Hard and APX-Hard, even if \( G \) is a DAG and if \( \alpha \) and \( \text{capa} \) are fixed.

**Proof.** As \( \alpha = \frac{1}{3} \) and \( \text{capa} = 3 \), there must be 3 clients in the taxi while it is driving through an arc of cost 1. Any taxi must then start at a node \( v_x \) for some \( s = (x,y,z) \in S \) and end at \( v'_y \), otherwise, there cannot be enough client in the taxi to satisfy any cost constraint. Let \( P_x \) be such a taxi. We now show that there is only one possible path \( P_x \) going from \( v_x \) to \( v'_y \). The taxi must go either to \( v'_x \) or \( w_x \) as it cannot reach another node with an arc of cost 0. If the taxi goes to \( w_x \) directly, it would have to drive through the arc \( (w_x, w'_x) \) of cost at least 1 with at most 2 clients and thus, would not satisfy the cost constraint of the clients \( c_s \) and \( d_x \). Consequently, the taxi \( P_x \) must pick up the clients \( c_s \) and \( d_x \), and goes to \( w'_x \) and \( v''_x \) to deliver \( c''_y \) and \( d_x \). Similarly, \( P_x \) must satisfy \( c''_y, d_y, c'''_z \) and \( d_z \) before reaching \( v'_y \).

A feasible solution can contain two taxis \( P_s \) and \( P_{s'} \) if and only if \( s_1 \cap s_2 \neq \emptyset \). Indeed, if, for instance, \( s_1 \cap s_2 = \{x\} \), the two taxis would have to pick up the
Figure 2: Example of reduction from (3DM). Every unspecified cost is 0. An optimal solution of (3DM) is 2: for example the sets $A$ and $C$. An optimal solution for max-DARP-M is 14 with two taxis, for example the taxi starting at $v_A$ and ending at $v_A'$ and the taxi from $v_C$ to $v_C'$.

same client $d_x$. Consequently, there is a feasible solution for $\mathcal{I}$ of size $K$ if and only if there is a feasible solution of $\mathcal{J}$ with $K$ taxis. As each taxi satisfies 7 clients, the solution satisfies $7K$ clients.

Let $M^* = \{s_1^*, s_2^*, \ldots, s_K^*\}$ be an optimal solution for $\mathcal{I}$ of size $K^*$. Then, an optimal solution $P^* = (P_{s_1}^*, P_{s_2}^*, \ldots, P_{s_K}^*)$ for $\mathcal{J}$ has $K^*$ taxis and satisfies $7K^*$ clients. If we assume there is a polynomial $\alpha$-approximation for max-DARP-
M, such an algorithm would return a feasible solution \( \mathcal{P} = (P_1, P_2, \ldots, P_K) \) satisfying \( 7K \) clients such that \( \alpha 7K^* \leq 7K \). Consequently, we could build in polynomial time a feasible solution \( \{s_1, s_2, \ldots, s_K\} \) for \( \mathcal{I} \) of size \( K \) such that \( \alpha K^* \leq K \). Thus, there is a polynomial \( \alpha \)-approximation for (3DM). As (3DM) is NP-Complete and APX-Complete and as \( G \) is a DAG in the reduction, this concludes the proof.

\[ \square \]

Remark 4. The previous proof can be adapted to any fixed values of \( \text{capa} \) and \( \alpha \) such that \( \text{capa} \geq \frac{1}{\alpha} \geq 3 \) by replacing every client \( d_x, d_y \) or \( d_z \) by \( \lceil \frac{1}{\alpha} \rceil - 2 \) clients. The nodes \( w_x \) and \( w'_x \) (similarly \( w_y \) and \( w'_y \) or \( w_z \) and \( w'_z \) would be replaced by two paths respectively containing the \( \lceil \frac{1}{\alpha} \rceil - 2 \) origins and the \( \lceil \frac{1}{\alpha} \rceil - 2 \) destinations of those new clients. Every arc of those paths would have a cost 0. And an arc of cost 1 would link the last origin to the first destination.

3.1.2. NP-Hardness when \( W \) is not bounded

We give, in this part, a proof that 1-DARP-M is NP-Complete, even if the graph is a DAG and if \( \alpha \) and \( \text{capa} \) are fixed.

The reduction. We prove a reduction from the partition problem (PART). Given a finite set of integers \( X = \{x_1, x_2, \ldots, x_n\} \), is it possible to part \([1; n]\) into two parts \( I \cup J \) such that \( \sum_{i \in I} x_i = \sum_{i \in J} x_i \). (PART) is weakly NP-Complete [9].

From an instance \( \mathcal{I} = (X) \) of (PART), we now build an instance \( \mathcal{J} = (G, (V_c, V_e, B_c, E_c), \omega, t, \text{capa}, \alpha) \) of 1-DARP-M where \( G \) is a DAG and where \( \text{capa} \) and \( \alpha \) are fixed. Let \( B = \sum_{x \in X} x/2 \). We fix \( \text{capa} = 2 \) and \( \alpha = \frac{1}{2} \). We define three main clients \( c_1, c_2 \) and \( c_3 \) going respectively from \( v_1 \) to \( v'_1 \), \( v_2 \) to \( v'_2 \) and \( v_3 \) to \( v'_3 \). We also define \( 2n \) clients \( d_{11}, d_{12}, \ldots, d_{1n} \) and \( d_{21}, d_{22}, \ldots, d_{2n} \). The client \( d_{i1} \) goes from \( w_{i1} \) to \( w_{i2} \).

The graph \( G \), the costs \( \omega \) and the times \( t \) are illustrated on Figure 3.

Figure 3: Example of reduction from (PART) to 1-DARP-M. On each arc \( a \), we write the values \( \omega(a) \) and \( t(a) \) in that order. If no number is given, the two values are 0.

The time window of \( c_2 \) is \([0, 0]\). The time window of \( c_3 \) is \([B, B]\). For all the other clients, the time window is \([0, B]\).

Theorem 3.2. 1-DARP-M is weakly NP-Complete even if \( G \) is a DAG and if \( \alpha \) and \( \text{capa} \) are fixed.

15
Proof. As \( \alpha = \frac{1}{2} \) and \( \text{capa} = 2 \), there must be 2 clients in the taxi while it is driving through an arc of cost 1. Consequently, the taxi must pick up the client \( c_1 \). In order to go to \( v_1' \), the taxi must drive through \( (v_2, v_2') \) and, then, must also pick up \( c_2 \). Similarly it must pick up \( c_3 \). For each \( i \in [1:n] \), either \( d_1^i \) or \( d_2^i \). Let \( I \) be the subset of \([1:n]\) such that \( i \in I \) if \( d_1^i \) is picked up.

Due to the time window of \( c_2 \), the taxi must arrive at \( v_2 \) at time 0 otherwise the time constraint cannot be satisfied. Similarly it must arrive at \( v_3 \) at time \( B \).

The moment when the taxi reaches \( v_3 \) is \( \sum_{i \in I} t(w_i, w_i') + \sum_{i \notin I} t(w_i, w_i') = \sum_{i \in I} x_i \). Thus, there exists a feasible taxi if and only if \( \sum_{i \in I} x_i = B = \sum_{i \notin I} x_i \). This concludes the proof.

From Theorem 3.2, we can deduce the following results.

**Corollary 3.1.** max-DARP-M and max-1-DARP-M are weakly NP-Hard and, unless \( W \) is polynomially bounded or \( P = NP \), cannot be approximated in polynomial time to within any variable ratio, even if \( G \) is a DAG and if \( \text{capa} \) and \( \alpha \) are fixed.

### 3.1.3. NP-Hardness and Parameterized Hardness with respect to the number of satisfied clients

If we search for a taxi satisfying exactly \( S \) clients, we can enumerate every subset of \( S \) clients and check if a taxi only satisfying that subset exists, and this give an XP algorithm for max-1-DARP-M and max-DARP-M with respect to \( S \). We prove in this subsection that a better algorithm is hardly to exist as max-1-DARP-M and max-DARP-M are \( W[1]-hard \) in \( S, \text{capa}, \alpha \) and \( W \).

We also demonstrate that the three problems, max-1-DARP-M, max-DARP-M and 1-DARP-M are NP-Complete and cannot be approximated in polynomial time even if \( W \) is fixed and that 1-DARP-M is \( W[1]-hard \) in \( \text{capa}, \alpha \) and \( W \).

*The reduction.* We describe an FPT-Reduction from the partitioned clique problem. Given an undirected graph \( G = (V = V_1 \uplus V_2 \uplus \cdots \uplus V_k, E) \) where \( V \) is partitioned into \( k \) independent sets, the partitioned clique problem consists in the search for a clique of size \( k \). Any such clique contains exactly one node in each part \( V_i \). This problem is NP-Complete and is \( W[1]-hard \) with respect to \( k \) [16].

From a parameterized instance \( G \) of the partitioned clique problem, we build an instance \( J \) of max-1-DARP-M such that the graph is a DAG. We consider that we remove the time constraint by setting \( t(a) = 0 \) for every arc \( a \in A \) and \( b_i = c_i = 0 \) for all \( i \) and, in that case, \( W = 1 \). While describing \( J \), we explain how the reduction works on a simple example, given in Figure 4.

Our goal is to create a directed acyclic graph \( H = (W \cup X, A) \).

\( W \) contains two nodes \( w_u^v \) and \( w_v'^u \) for each edge \((u, v)\) of \( G \). It is partitioned into \( k \) layers and each layer is partitioned into \( k-1 \) sublayers. We write \( W_i \) for layer \( i \). The sublayers of layer \( i \) are numbered from 1 to \( k \) except \( i \) and we write \( W_i^j \) for sublayer \( j \) of layer \( i \). For each edge \{u, v\} in \( E \) such that \( u \in V_i \)
and \( v \in V_j \) and \( i < j \), we add a client \( c^v \) with the origin \( w^v_u \in W^j_i \) and the destination \( w^v_v \in W^j_j \).

Each sublayer is a stable set. A node \( w^v_u \in W^j_i \) is linked to a node \( w^v_v \) of the next sublayers of \( W_i \) (\( W_i^{j+1} \) if \( j \neq i - 1 \), \( W_i^{j+1} \) otherwise) if \( u_1 = u_2 \). Note that this common node is necessarily in \( V_i \). Note also that each layer is an acyclic graph.

\( X \) is a set of \( k - 1 \) paths. For each \( i \in \{1; k-1\} \), we add to \( H \) a path \([x^i_1, x^i_2, \ldots, x^i_l, x^i_i', x^i_2', \ldots, x^i_l'] \) where \( d_i = \frac{(k-1)\cdot k}{2} - i \cdot (k-i) \). We also add \( d_i \) clients \( D_i = \{d^i_1, d^i_2, \ldots, d^i_d\} \). Each client \( d^i \) goes from \( x^i_1 \) to \( x^i_l' \). Let \( X_i \) be the set of origins of those clients and \( X_i' \) be the set of destinations. All the nodes of the last sublayer of each layer \( W_i \), for \( i \neq k \), are linked to \( x^i_1 \), and, similarly, \( x^i_l' \) is linked to all the nodes of the first layer of \( W_{i+1} \).

We can easily see that \( H \) does not contain a circuit as each layer \( W_i \) is acyclic and as it is only connected to the following layer with the path \( X_i \cup X'_i \).

The cost of every arc \((x^i_1, x^i_l')\) is 1. For every other arc, the cost is null.

Finally, we set \( S = \frac{(k-1)\cdot k}{2} + \sum_{p=1}^{k-1} d_p \), \( \text{capa} = \frac{(k-1)\cdot k}{2} \) and \( \alpha = \frac{1}{\text{capa}} \). Any taxi driving through an arc of cost non-zero must contains \( \text{capa} \) clients otherwise the cost constraint cannot be satisfied.

We only give, in this section, the key idea of the reduction. The formal proof is given in Appendix A.

Key idea of the reduction. Firstly, we assume we search for a taxi satisfying \( S \) clients. That taxi must satisfy exactly one client per sublayer and all the clients of \( D_i \). The way \( H \) is built make the taxi do a choice: while traversing the \( k - 1 \) sublayers of \( W_i \), the taxi must choose a node \( v_i \) of \( V_i \) because each such node is associated with a connected component of the layer \( W_i \). For example, the component of 4 in Figure 4, represented with dotted nodes, is \( \{w^1_3, w^2_4, w^3_6\} \).

While driving through a node containing 4 in \( W^1_3 \), it is not possible anymore to go to a node containing 3 or 5 in \( W^2_3 \) or \( W^2_5 \). Thus, it is not possible to drive to a node containing 3 or 5 in any other set, because this would mean that a client is picked up and not delivered. Thus, the taxi must choose one node \( v_j \) per set \( V_j \). Consequently, the taxi build a set \( C = \{v_i \in V_i, i \in \{1; n\}\} \). While crossing the \( k - 1 \) sublayers of \( W_i \), it must also choose \( k - 1 \) edges of \( G \), one incident edge to \( v_i \) for each of the \( k - 1 \) sets corresponding to the index \( i \). Each of those edges selects a node of a set \( V_j \), for \( j \neq i \). This node is \( v_j \) for each \( j \) if and only if the set \( C \) is a clique. For example, a valid taxi corresponding to the clique \( \{2, 5, 7\} \) is drawn in Figure 4 with bold arcs and nodes. If, on the other hand, the taxi chooses to start with the nodes \( w^3_4 \) and continue with \( w^3_7 \), then it must continue to \( w^3_7 \) in order to satisfy the client \( c^6_4 \). It is then not possible to satisfy three clients: either it drives \( c^6_4 \) to his destination or forget this client and drives \( c^6_4 \). This is due to the fact that the taxi must choose a node of \( W^3_4 \) containing 4 but the edge \( \{4, 7\} \) does not exists in \( G \) thus, the taxi must choose another node.

Secondly, in order to go from one layer \( W_i \) to the following layer, a taxi must
Figure 4: Example of reduction from the Partitioned Clique problem. There are 3 stable sets in $G$: $V_1$, $V_2$, and $V_3$; and 6 sublayers in $H$: $W_1^1$, $W_1^2$, $W_1^3$, $W_2^1$, $W_2^2$, and $W_3^2$. Each layer is separated from the other with an horizontal dashed line. The two paths of $X$ are on the right.

Note that there are dashed lines joining the origin and the destination of each client for information. Those lines are not edges or arcs of the graph. Every cost which is not specified is 0.

The two paths of $X$ are on the right.

Note that there are dashed lines joining the origin and the destination of each client for information. Those lines are not edges or arcs of the graph. Every cost which is not specified is 0.

go through the path $X_i \cup X_i'$ and thus it must go through an arc of cost 1. When this happens, as $\alpha = \frac{1}{\text{capa}}$, the taxi must be full: it must picks up every clients of $D_i$. For example, in Figure 4, $\text{capa} = 3$. Any taxi must picks up the clients $d_1^1$ and $d_2^1$ in order to go through $(x_1^1, x_1'^1)$ and $(x_2^1, x_2'^1)$. Thus there cannot be more than one taxi in a feasible solution otherwise the two taxis must satisfy some same clients and this is not allowed. Consequently, a feasible solution satisfying $S$ clients can contain only one taxi.

Finally, a taxi must satisfy $S$ clients. Indeed, it must pick up a client from
$W^k_1$ and delivers it at $W^k_1$. Otherwise there is no way for it to pick up $\text{capa}$ clients before going through an arc of cost 1. Thus it must satisfy exactly one client per set $W^j_i$ and all the clients of every set $D_i$.

**Theorem 3.3.** Even if $G$ is a DAG,

- $1$-$\text{DARP-M}$ is $W[1]$-hard with respect to capa, $\alpha$ and $W$;
- $\text{max-DARP-M}$ and $\text{max-1-DARP-M}$ are $W[1]$-hard with respect to $S$, capa, $\alpha$ and $W$;
- $1$-$\text{DARP-M}$ is NP-Complete and $\text{max-DARP-M}$, $\text{max-1-DARP-M}$ are NP-Hard and cannot be approximated in polynomial time to within any variable ratio even if $W$ is fixed.

The proof of this theorem is given in Appendix A.

### 3.2. Parameterized algorithms

In this section, we first give an algorithm to solve max-1-DARP-M in a DAG in pseudopolynomial time when capa is fixed. We then deduce a $\sqrt{n}$-approximation algorithm for max-DARP-M in a DAG in pseudopolynomial time when capa is fixed.

#### 3.2.1. A parameterized algorithm for max-1-DARP-M

We consider an instance $I = (G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha)$ with $n$ clients and where $G$ is a DAG. We assume that, in $G$, there is a path from any origin $v_i \in V_c$ to the corresponding destination $v'_i \in V'_c$: there is no path from $v'_i$ to $v_i$. We finally consider that there is no intermediate point: $V = V_c \cup V'_c$. Every arc $(u, v)$ corresponds to a shortest path from $u$ to $v$ in the road network if such a path exists.

**Definition 2.** We now define an auxiliary graph $S(I)$ in which each node is associated with a state corresponding to the taxi leaving a node $u \in V$ at time $t$ with a set $S$ of at most $\text{capa}$ clients and such that $\kappa$ clients already entered the taxi (including the clients who have left the taxi and the clients who have not); we write that state $w(u, t, S, \kappa)$, $u \in V$, $t \in [b_i, e_i]$ if $u = v_i$ or if $u = v'_i$, $S \subset [1; n]$, $|S| \leq \text{capa}$, $\kappa \in [1; n]$. An arc is a transition between two states: we add an arc $(w(u_1, t_1, S_1, \kappa_1), w(u_2, t_2, S_2, \kappa_2))$ in $S(I)$ if and only if all the following three properties are true:

1. $S_1 \neq \emptyset$
2. there is a path from $u_1$ to $u_2$ in $G$;
3. $t_2 - t_1 = t(u_1, u_2)$
4. either $u_2$ is the origin $v_i$ of client $i$, $S_2 = S_1 \cup \{i\}$ and $\kappa_2 = \kappa_1 + 1$
   - or $u_2$ is the destination $v'_i$ of client $i$, $S_1 = S_2 \cup \{i\}$ and $\kappa_2 = \kappa_1$
Figure 5: Example of transformation from $\mathcal{I}$ to the auxiliary graph $S(\mathcal{I})$. For readability, we do not consider, in this figure, the time windows, and some states like $w(v_3, t, 3, 1)$ or $w(v_4, t, 4, 1)$ are missing. The weight of each arc $a$ on the upper graph is the cost $\omega(a)$. For each state $w(u, t, S, \kappa)$ contains $u$, $S$ and $\kappa$ respectively on the lower left part, the upper part and the lower right part of the node. The time $t$ is not given.

An example is given in Figure 5.

As the existence of an arc between two states $w(u_1, t_1, S_1, \kappa_1)$ and $w(u_2, t_2, S_2, \kappa_2)$ implies that there is a path from $u_1$ to $u_2$ in $G$ and as $G$ is a DAG, we can deduce the following property.

**Property 1.** $S(\mathcal{I})$ is a DAG.

We now introduce Algorithm 1, which solves max-1-DARP-M using the auxiliary graph $S(\mathcal{I})$. We then prove the polynomial time complexity and the correctness of the algorithm.

For each node $w = (v, t, S, \kappa) \in S(\mathcal{I})$, we define a set $\mathcal{P}(w)$ of mappings associating to each client of $S$ a non negative real: each mapping represents a
Definition 3. Let \( w = (v, t, S, \kappa) \in \mathcal{S}(I) \), and \( p \) and \( p' \) be two mappings of \( \mathcal{P}(w) \). We say \( p \) dominates \( p' \) if, for every client \( i \) in \( S \), \( p(i) \leq p'(i) \). We write \( p \preceq p' \).

We use Algorithm 1 to compute all the sets of mappings of the auxiliary graph and to deduce a feasible solution for \( I \).

Each set \( \mathcal{P}(w) \) is built recursively using the sets of mappings of all pre-decessors of \( w \). In order to simplify Algorithm 1, we define, for each arc \((w_1, w_2) \in \mathcal{S}(I)\), a set of intermediate mappings \( \mathcal{P}(w_1, w_2) \) which can be seen as the subset of \( \mathcal{P}(w_2) \) built from the state \( w_1 \) with useful additional information. This set is built with the SUBMAP function, described in Algorithm 2. In addition, a BUILD function is given in Algorithm 3 to build a solution. Table 2 illustrates some iterations of the algorithm on the example given in Figure 5.

---

**Algorithm 1 Main algorithm**

**Require:** an instance \( I = (G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha) \) of max-1-DARP-M  

**Ensure:** an optimal solution for \( I \)

1. Build the auxiliary graph \( \mathcal{S}(I) \)
2. For each \( i \in \lfloor 1;n \rfloor \) and \( t \in \lfloor b_i, e_i \rfloor \) Do  
   3. \( p_i \leftarrow \) a mapping associating 0 to the client \( i \)
   4. \( \mathcal{P}(w(v_i, \{i\}, 1)) \leftarrow \{p_i\} \)
   5. \( \text{pred}(p_i) \leftarrow \text{null} \)
3. \( L \leftarrow \) a topological ordering of \( \mathcal{S}(I) \backslash \{w(v_i, \{i\}, 1) | i \in \lfloor 1;n \rfloor \} \)
4. For each \( w = w(v, t, S, \kappa) \in L \) Do  
   5. \( \mathcal{P}(w) \leftarrow \emptyset \)
   6. For each predecessor \( w^- = w(v^-, t^-, S^-, \kappa^-) \) of \( w \) Do  
      7. \( \mathcal{P}(w^-, w) \leftarrow \text{SUBMAP}(I, \mathcal{S}(I), (w^-, w), \mathcal{P}(w^-)) \)
   8. For each \( (p, w^-, p^-) \in \mathcal{P}(w^-, w) \) Do  
      9. If For all \( p' \in \mathcal{P}(w) \), \( p' \not\preceq p \) Then  
         10. remove from \( \mathcal{P}(w) \) every mapping \( p' \) such that \( p \preceq p' \)
         11. add \( p \) to \( \mathcal{P}(w) \)
         12. \( \text{pred}(p) \leftarrow (w^-, p^-) \)
   13. \( T \leftarrow \{w = w(v^'_i, t, \emptyset, \kappa)|i, \kappa \in \lfloor 1;n \rfloor, \mathcal{P}(w) \neq \emptyset\} \)
   14. If \( T = \emptyset \) Then Return no solution.
   15. \( \tau \leftarrow \text{argmax}\{\kappa|w(v^'_i, t, \emptyset, \kappa) \in T\} \)
   16. \( p \leftarrow \) a mapping of \( \mathcal{P}(\tau) \)
17. Return BUILD\((I, \mathcal{S}(I), \text{pred}, \tau, p)\)

---

Due to the length of this part, we put the proof of correctness of Algorithm 1 in Appendix B.

The end of this part is dedicated to proving that, for every node \( w = (v, t, S, \kappa) \in \mathcal{S}(I) \), the size of \( \mathcal{P}(w) \) is polynomial if \( \text{capa} \) is fixed and if \( W \) is
Algorithm 2 SUBMAP Function

Require: an instance $I = (G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha)$ of max-1-DARP-M, the auxiliary graph $S(I)$, an arc $(w_1 = w(u_1, t_1, S_1, \kappa_1), w_2 = w(u_2, t_2, S_2, \kappa_2)) \in S(I)$, a set $P(w_1)$ of mappings from $S_1$ to $\mathbb{R}^+$

Ensure: a set $P(w_1, w_2)$ of mappings from $S_2$ to $\mathbb{R}^+$

1: function SUBMAP($I, S(I), (w_1, w_2), P(w_1)$)
2: $P(w_1, w_2) \leftarrow \emptyset$
3: For each mapping $p_1 \in P(w_1)$ Do
4: Initialize a mapping $p_2$ of $S_2 \rightarrow \mathbb{R}^+$
5: For each client $i \in S_1$ Do
6: If $p_1(i) + \frac{\omega(u_1, w_2)}{|S_1|} \leq \alpha \cdot \omega(v_i, v'_i)$ Then
7: If $i \in S_2$ Then $p_2(i) \leftarrow p_1(i) + \frac{\omega(u_1, w_2)}{|S_1|}$
8: Else
9: Continue loop For at Line 3
10: If $S_2$ contains a client $i$ not in $S_1$ Then, $p_2(i) = 0$
11: Add $(p_2, w_1, p_1)$ to $P(w_1, w_2)$
12: Return $P(w_1, w_2)$

Algorithm 3 BUILD Function : Build a partial solution from a selected node.

Require: an instance $I = (G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha)$ of max-1-DARP-M, the auxiliary graph $S(I)$, a predecessor function $\text{pred}$, a node $w = w(u, t, S, \kappa) \in S(I)$ and a mapping $p$ of $P(w)$

Ensure: an path ending at $u$ in $G$

1: function BUILD($I, S(I), \text{pred}, w, p$)
2: $P \leftarrow \{u\}$
3: If $\text{pred}(p) \neq \text{null}$ Then
4: $(w^-, p^-) \leftarrow \text{pred}(p)$
5: $P \leftarrow P \cup \text{BUILD}(I, S(I), \text{pred}, w^-, p^-)$
6: Return $P$
bounded by polynomial in $|\mathcal{I}|$, and deduce that Algorithm 1 is XP with respect to \textit{capa} when $W$ is polynomially bounded.

**Definition 4.** Let $w = (v,t,S,\kappa) \in S(\mathcal{I})$, for every subset $I \subseteq S$, we define $p_{\mid I}$ as the subvector of $p$ restricted to every client of $I$. The set $\mathcal{P}(w,I)$ is the subset of pareto optimal vectors of $\{p_{\mid I}, p \in \mathcal{P}(w)\}$, i.e. for any two distinct mappings $p$ and $p'$ of $\mathcal{P}(w,I)$, $p \not\geq p'$ and $p' \not\geq p$.

Note that $\mathcal{P}(w,S) = \mathcal{P}(w)$ due to Lines 12 and 13 of Algorithm 1.

We want to prove the following properties:

**Property 2.** Let $w = (u,t,I \cup J, \kappa) \in S(\mathcal{I})$, with $|J| \geq 2$, and if $u$ is the origin of a client in $I$, then $|\mathcal{P}(w,I)| \leq n^{(\text{\textit{capa}} - 1) \cdot (|I| - 2)} \cdot W^{|I| - 2}$.

**Property 3.** Let $w = (u,t,I \cup J, \kappa) \in S(\mathcal{I})$, with $|J| \geq 1$, and if $u$ is not the origin of any client in $I$ then $|\mathcal{P}(w,I)| \leq n^{(\text{\textit{capa}} - 1) \cdot (|I| - 1)} \cdot W^{|I| - 1}$.

We prove the two properties by induction on the size of $|I|$. Each property alternatively proves the other one. The following lemmas proves that Property 3 is true when $|I| = 1$, that if Property 3 is true when $|I| \leq s$ for some constant $s$, then Property 2 is true when $|I| = s + 1$, and, finally, when Property 2 is true when $|I| \leq s$ for some constant $s$, then Property 3 is true when $|I| = s$.

**Lemma 3.1.** Property 3 is true when $|I| = 1$. 

---

Table 2: Example of iterations of the For loop at Line 7 of Algorithm 1 on the instance given in Figure 5. We assume that every duration $t(a)$ is 0 and that every time window contains 0.

</tbody>
</table>
Proof. Let \( I = \{ i \} \). In that case, every mapping of \(|P(w, I)|\) maps some positive real to the client \( i \). There can be only one pareto optimal mapping: the one associating the smallest real to \( i \).

Lemma 3.2. If, for some constant \( s \leq \text{capa} \), Property 3 is true when \( 1 \leq |I| \leq s \), then Property 2 is true when \(|I| = s+1\).

Proof. Let \( w = w(u, t, I \cup J, \kappa) \), we assume \( I = \{ i_1, i_2, \ldots, i_{s+1} \} \). We assume that \( u \) is the origin of some client in \( I \) and, in any topological ordering of \( G \), \( v_i \) is before \( v_k \) if and only if \( j \leq k \). Then \( w = v_{i_{s+1}} \) and for any mapping \( p \) of \( P(w) \), \( p(i_{s+1}) = 0 \). If we consider two mappings \( p \) and \( p' \) of \( P(w) \), \( p_{1\setminus i_{s+1}} \leq p'_{1\setminus i_{s+1}} \) if and only if \( p_{1\setminus i} \leq p'_{1\setminus i} \). Thus, \( |P(w, I)| = |P(w, I\setminus i_{s+1})| \). By the hypothesis, \(|P(w, I\setminus i_{s+1})| \leq \eta^{(\text{capa}-1)(s-1)} \cdot W^{s-1} = \eta^{(\text{capa}-1)(|I|-2)} \cdot W^{|I|-2} \). Thus Property 2 is proved for \( I \).

In order to prove the last lemma, we first prove an intermediate result.

Definition 5. Using the \( \text{pred} \) array, we can define a precedence tree of mappings in which \( p^- \) is linked to \( p \) if \( \text{pred}(p) = (w^-, p^-) \) for some state \( w^- \). Let \( w_1 = w(u_1, t_1, I \cup J_1, \kappa_1) \) and \( w_2 = w(u_2, t_2, I \cup J_2, \kappa_2) \) such that there is a path from \( w_1 \) to \( w_2 \) in \( S(I) \). We say that a mapping \( p_1 \) of \( P(w_1) \) generates \( p_2 \) of \( P(w_2) \) if there is a path of mappings from \((w_1, p_1)\) to \((w_2, p_2)\) in the precedence tree.

Lemma 3.3. Let \( w_1 = w(u_1, t_1, I \cup J_1, \kappa_1) \) and \( w_2 = w(u_2, t_2, I \cup J_2, \kappa_2) \) such that there is a path from \( w_1 \) to \( w_2 \) in \( S(I) \). Let \( q_1 \) be a mapping of \( P(w_1, I) \) and \( p_1 \) and \( p'_1 \) be two mappings of \( P(w_1) \) such that \( p_{1\setminus I} = q_1 \) and \( p'_{1\setminus I} = q_1 \). Let \( p_2 \) and \( p'_2 \) be two mappings of \( P(w_2) \) such that \( p_1 \) generates \( p_2 \) and \( p'_1 \) generates \( p'_2 \). Let finally \( q_2 \) and \( q'_2 \) be \( p_2 \setminus I \) and \( p'_2 \setminus I \). Then \( q_2 \leq q'_2 \) or \( q'_2 \leq q_2 \).

Proof. We first assume that \( w_1 \) is a predecessor of \( w_2 \). Note that, due to Algorithm 2 at Line 7, \( p_2(i) - p_1(i) = p'_2(i) - p'_1(i) = \frac{u(u_i, w_2)}{\capa} \) for every client \( i \in I \subset S_1 \). Since \( p_{1\setminus I} = p'_{1\setminus I} = q_1 \), \( p_1(i) = p'_1(i) = q_1(i) \) and then \( q_2(i) = p_2(i) = p'_2(i) = q'_2(i) \).

We can similarly show the same property if \( w_1 \) is an ancestor of \( w_2 \) instead of just a predecessor. In that case, there are intermediates mappings between \( p_1 \) and \( p_2 \), and between \( p'_1 \) and \( p'_2 \). There is a path \((w_1 = x_1, x_2, \ldots, w_2 = x_l)\) such that \( p_1 \) generates a mapping \( p_{x_2} \) of \( x_2 \) which generates a mapping \( p_{x_3} \) of \( x_3 \), \ldots There is also a path \((w_2 = x'_1, x'_2, \ldots, w_2 = x'_k)\) such that \( p'_1 \) generates a mapping \( p'_{x'_2} \) of \( x'_2 \) which generates a mapping \( p'_{x'_3} \) of \( x'_3 \), \ldots Let \( x_i = w(u_i, t_i, S_i, \kappa_i) \) and \( x_i' = w(u_i', t_i', S_i', \kappa_i') \). Due to Algorithm 2 at Line 7, \( p_2(i) - p_1(i) = \sum_{i=1}^{l-1} \frac{u(u_i, w_2)}{|S_i|} \) and \( p'_2(i) - p'_1(i) = \sum_{i=1}^{l-1} \frac{u(u_i', w_2')}{|S_i'|} \). Since \( p_{1\setminus I} = p'_{1\setminus I} = q_1 \), for all \( i \in I \), \( p_1(i) = p'_1(i) = q_1(i) \) and then depending whether \( \sum_{i=1}^{l-1} \frac{u(u_i, w_2)}{|S_i|} \geq \sum_{i=1}^{l-1} \frac{u(u_i', w_2')}{|S_i'|} \) or not, either for all \( i \in I \), \( q_2(i) \geq q'_2(i) \) or for all \( i \in I \), \( q_2(i) < q'_2(i) \).
Lemma 3.4. If, for some constant $s \leq \text{capa}$, Property 2 is true when $2 \leq |I| \leq s$, then Property 3 is true when $|I| = s$.

Proof. Let $w = w(u, t, I \cup J, \kappa)$, we assume $I = \{i_1, i_2, \ldots, i_s\}$ and $u$ is not the origin of any client in $I$.

Let $A = \bigcup_{t' \in [a_i, b_i]} \bigcup_{J' \subseteq [1:m]} \bigcup_{|J'| \leq \text{capa} - |I|} \bigcup_{\kappa' \in [1:n]} \mathcal{P}(w(v_{i_1}, t', I \cup J', \kappa'), I)$.

We want to prove that $|\mathcal{P}(w, I)| \leq |A|$.

We define a function $\text{anc}$ associating to each mapping of $\mathcal{P}(w, I)$ a mapping of $A$. Let $q$ be a mapping of $\mathcal{P}(w, I)$. There exists a mapping $p$ of $\mathcal{P}(w)$ such that $q = p[I]$. Thus there exists an ancestor $w_s = w(v_{i_s}, t', I \cup J', \kappa')$ of $w$ in $\mathcal{S}(I)$ and a mapping $p_s$ of $\mathcal{P}(w_s)$ such that $p_s$ generates $p$. Let $\text{anc}(q) = p[I]$.

If $|\mathcal{P}(w, I)| > |A|$, there exist two mappings $q_1$ and $q_2$ in $\mathcal{P}(w, I)$ such that $\text{anc}(q_1) = \text{anc}(q_2)$. By Lemma 3.3, $q_1 < q_2$ or $q_2 < q_1$. There is a contradiction because every mapping of $\mathcal{P}(w, I)$ is Pareto optimal. Consequently $|\mathcal{P}(w, I)| \leq |A|$.

$$|\mathcal{P}(w, I)| \leq |A| \leq \sum_{t' \in [a_i, b_i]} \sum_{J' \subseteq [1:m]} \sum_{|J'| \leq \text{capa} - |I|} \sum_{\kappa' \in [1:n]} |\mathcal{P}(w(v_{i_1}, t', I \cup J', \kappa'), I)|$$

$$\leq (W \cdot n^{\text{capa} - 2} \cdot n) \cdot (n^{\text{capa} - 1} \cdot (|I| - 2) \cdot W^{|I| - 2})$$

Thus Property 3 is proved for $I$. $\square$

Lemma 3.5. Algorithm 1 is pseudo XP with respect to capa.

Proof. We assume $\text{capa}$ are fixed and want to prove that the algorithm is polynomial in $|I|$ and $W$. Note firstly that the size of $\mathcal{S}(I)$ is $O(n \cdot W \cdot n^{\text{capa}} \cdot n)$.

Secondly, Lemmas 3.1, 3.2 and 3.4 prove by induction that Properties 2 and 3 are true. Thus, for each node $w \in \mathcal{S}(I)$, the size of $\mathcal{P}(w)$ is at most $W^{\text{capa}} \cdot n^{\text{capa} \cdot \text{capa}}$.

The number of iterations of the loops of Algorithm 1 and the complexity of each operation inside the loops depend polynomially on $n$ and $W$, $\mathcal{S}(I)$ or $|\mathcal{P}(w)|$ for some node $w \in \mathcal{S}(I)$. Thus, the algorithm is polynomial. $\square$

By Lemma B.1 (proved in Appendix B) and 3.5, we prove the following theorem.

Theorem 3.4. If $G$ is a DAG, max-1-DARP-M is pseudo XP in capa.
### 3.2.2. A parameterized approximation for max-DARP-M

**Corollary 3.2.** If \( G \) is a DAG, there is a \( \frac{1}{\sqrt{n}} \)-approximation for max-DARP-M in time pseudo XP with respect to \( \text{capa} \).

**Proof.** We use Algorithm 4.

**Algorithm 4**

**Require:** An instance \( I = (G, (V_c, V'_c, B_c, E_c), t, \omega, \text{capa}, \alpha) \) of max-DARP-M

**Ensure:** A feasible solution for \( I \)

1. \( \mathcal{P} \leftarrow \emptyset \)
2. loop
3. \( I_1 \leftarrow \) the instance of max-1-DARP-M with the same parameters as \( I \)
4. \( P \leftarrow \) an optimal solution for the instance \( I_1 \) of max-1-DARP-M
5. If \( P = \emptyset \) Then Return \( \mathcal{P} \)
6. Else
7. Insert \( P \) into \( \mathcal{P} \)
8. Remove every client satisfied by \( P \) from \( I \).

If \( G \) is a DAG and as \( \text{capa} \) is a fixed parameter, we can compute the taxi \( P \) at Line 4 in pseudopolynomial time by Theorem 3.4. Consequently, Algorithm 4 is pseudopolynomial.

We define \( s(P) \) as the number of clients that are driven by the taxi \( P \). Let \( P^* = (P_1^*, P_2^*, \ldots, P_q^*) \) be an optimal solution for \( I \) and let \( \mathcal{P} = (P_1, P_2, \ldots, P_r) \) be the solution returned by Algorithm 4. We now show the following property:

**Property 4.** Either \( P^* \) and \( \mathcal{P} \) are empty or

\[
\frac{\sum_{i=1}^{q} s(P_i^*)}{\sum_{i=1}^{r} s(P_i)} \leq \sqrt{\frac{q}{r}}.
\]

Note that \( \mathcal{P} \) is empty if and only if \( P^* \) is empty. We just have to assume that \( \mathcal{P} \neq \emptyset \) and prove the second part of the property. Finally, note that Property 4 implies that Algorithm 4 is a \( \frac{1}{\sqrt{n}} \)-approximation algorithm as \( \sum_{i=1}^{q} s(P_i^*) \leq n \).

We prove Property 4 by induction on \( n \), the number of clients.

**Basis:** if there are 2 clients, then, there cannot be more than one taxi in a feasible solution for \( I : q = r = 1 \). Consequently, the optimal solutions for \( I \) and for \( I_1 \) are the same. Thus, \( \frac{s(P_1^*)}{s(P_1)} = 1 \leq \sqrt{2} = \sqrt{s(P_1^*)} \). Consequently, Property 4 is proved in that case.

**Inductive Step:** We now assume that the property is true for every instance with \( n \) clients or less. Let \( I \) be an instance with \( n + 1 \) clients. Let \( l \) be the number of taxis in \( \mathcal{P}^* \) with a non empty intersection with \( P_1 \). Without loss of generality, we renumber those taxis \( (P_1^*, P_2^*, \ldots, P_l^*) \). Note that \( l \leq s(P) \) because a client cannot be satisfied by two taxis in \( \mathcal{P}^* \), thus, there cannot be more than \( s(P) \) taxis intersecting \( P \). In addition, note that \( l \leq q \).
As $P_1$ is an optimal solution of $I_1$ and as every taxi in $P^*$ is a feasible solution of $I_1$, 
\[
\frac{\sum_{i=1}^{l} s(P^*_i)}{s(P_1)} \leq \frac{l \cdot s(P_1)}{s(P_1)} \leq l 
\leq s(P_1)
\]

Consequently,
\[
\sum_{i=1}^{l} s(P^*_i) \leq s(P_1) \quad (7)
\]

If $l = q$, then the property is proved.

Otherwise, let $J$ be the instance $I$ where every client satisfied by $P_1$ is removed. Note that, this instance is exactly the instance Algorithm 4 is working on at the beginning of the second of iteration. Consequently, if we directly run Algorithm 4 on instance $J$, it returns $(P_2^*, P_3^*, \ldots, P_r^*)$.

Let $Q^*$ be an optimal solution of $J$. Note that, as $l \neq q$, $(P^*_{l+1}, P^*_{l+2}, \ldots, P^*_q)$ is not empty, and as it is a feasible solution for $J$, $Q^*$ is not empty. In addition, $r \geq 2$. By the inductive hypothesis,
\[
\frac{\sum_{Q^* \in Q^*} s(Q^*)}{\sum_{i=2}^{r} s(P_i)} \leq \sqrt{\sum_{Q^* \in Q^*} s(Q^*)}
\]

\[
\sqrt{\sum_{Q^* \in Q^*} s(Q^*)} \leq \sum_{i=2}^{r} s(P_i)
\]

As $(P^*_{l+1}, P^*_{l+2}, \ldots, P^*_q)$ is a feasible solution for $J$,
\[
\sqrt{\sum_{i=l+1}^{q} s(P^*_i)} \leq \sum_{i=2}^{r} s(P_i)
\]

By equation (7),
\[
\sqrt{\sum_{i=1}^{l} s(P^*_i)} + \sqrt{\sum_{i=l+1}^{q} s(P^*_i)} \leq \sum_{i=1}^{r} s(P_i)
\]
Finally, note that if \( A > 0 \) and \( B > 0 \), then \( \sqrt{A + B} \leq \sqrt{A} + \sqrt{B} \).

\[
\sqrt{\sum_{i=1}^{q} s(P_i^*)} \leq \sqrt{\sum_{i=1}^{r} s(P_i)}
\]

The inductive step is proved. Consequently, Property 4 is proved too and this concludes the proof of the corollary.

**Remark 5.** The proof of Corollary 3.2 proves also that the smaller the optimal solution is, the better the approximation ratio is.

### 4. Conclusion

We have studied a taxi sharing problem in which the price of a trip is evenly shared between the passengers of the trip. The bill of the passengers must be reduced by a given factor \( \alpha \). In addition, the taxi must satisfy a capacity constraint and a time window constraint. We defined two optimization problems, max-DARP-M and max-1-DARP-M, and a decision problem 1-DARP-M and studied the parameterized complexity and approximability of those problems. It seems that the cost constraint affects the complexity of the problem more than the time constraint. Note that the time constraint make the problems weakly hard: when the width of the time windows are polynomially bounded and when the cost constraint is removed, the problems are polynomial. On the contrary, even if the time constraint is removed and if all the parameters are fixed, the problems are hard to solve.

We showed that there exists a pseudopolynomial algorithm for max-1-DARP-M and 1-DARP-M if the capacity \( \text{capa} \) of the taxis is fixed and if the road network is acyclic. This algorithm makes it possible to build a \( \frac{1}{\sqrt{n}} \)-approximation for max-DARP-M. However, considering its time complexity, this algorithm seems unpractical without any implementation improvement.

Some questions remain open: what is the parameterized complexity and approximability of the three problems with respect to \( \alpha \) or to \( \alpha \) and \( W \)?, and is there a constant factor parameterized approximation for max-DARP-M in \( \text{capa} \)?

To conclude, max-1-DARP-M seems too hard to be solved in practice and it looks like the cost constraint is the main cause of that. We think this constraint is hard because it is independently defined for each client. A way to simplify it could be to define a unique constraint for all the clients or for all the clients of a same taxi. In the current model, every client cannot pay more than \( \alpha \) multiplied by the cost of a private ride. Instead of that constraint, we could ask all the clients of a same taxi to not pay more than the sum of all their private rides multiplied by \( \alpha \). If we then fairly divide the cost of the ride, no client would pay more than \( \alpha \) multiplied by the cost of a private ride. Note that some of the clients would not pay exactly the cost of their own ride but also a part of the rides of the other clients.

Appendix A. Proof of the reduction of Theorem 3.3

This appendix is dedicated to the proof of Theorem 3.3 by formally proving the reduction given in Subsubsection 3.1.3. We first show two intermediates lemmas.

**Lemma A.1.** A feasible taxi picks up a client in \( W^j_i \), for some \( i < j \), and delivers it in \( W^j_j \) if and only if it goes through every path \( X_l \) including the arc \( (x^{d_l}, x^{l'}) \) for \( l \in \llbracket i; j-1 \rrbracket \).

**Proof.** We first demonstrate that the taxi picks up a client in \( W^j_j \), for some \( i < j \), and delivers it in \( W^j_j \) if and only if it goes through every path \( X_l \) including the arc \( (x^{d_l}, x^{l'}) \) for \( l \in \llbracket i; j-1 \rrbracket \). The necessary condition follows from the fact that any path from \( W^j_i \) to \( W^j_j \) goes through those paths.
We now assume there is a feasible route of a taxi in $H$ not containing any node of $W_i^j$ and that this taxi goes through $(x_i^d, x_i^l)$ for some $l \in [i; j - 1]$. The clients that can go through that arc $(x_i^d, x_i^l)$ are those for which the origin is before $x_i^d$ and the destination is after $x_i^l$ in a topological ordering of $H$. There are firstly the $d_i$ clients of $D_i$. There are secondly the clients coming from sublayer $W_q^i$ to sublayer $W_q^i$ where $p \leq l$ and $q > l$ except if $p = i$ and $q = j$ because the taxi does not drive any client from $W_i^j$. There are $l \cdot (k - l) - 1$ such couples of sublayers. As there is no more than one client per sublayer in a path of $H$, there cannot be more than $d_i + i \cdot (k - i) - 1$ clients in a route of a taxi going through $(x_i^d, x_i^l)$. As $d_i = \frac{(k - 1) \cdot k}{2} - i \cdot (k - i)$ and $\text{capa} = \frac{(k - 1) \cdot k}{2}$, there can be at most $\text{capa} - 1$ clients in the taxi. However $\alpha = \frac{1}{\text{capa}}$, the taxi cannot go through an arc of cost 1 with less than $\text{capa}$ clients. Thus, the taxi cannot drive through any arc $(x_i^d, x_i^l)$ for $l \in [i; j - 1]$.

\begin{lemma}
If there is a clique $C$ of size $k$ in $G$, there is a feasible solution for $J$ satisfying $S$ clients.
\end{lemma}

\begin{proof}
If there is a clique $C$ of size $k$ in $G$, then, let $u_i$ be the node of $C \cap V_i$. We define the subgraph $P$ of $H$ such that, for each $i < j \in [1; k]$, $P$ contains one node per sublayer, the origin and the destination of the client $c_{a_i^j}$, and all the paths $X_i \cup X'_i$. There is always in $P$ an arc linking two nodes $w_u^i$ and $w_y^i$ of two consecutive sublayers of $W_i$ because $u = x = u_i$. Thus, $P$ is a path.

$P$ satisfies the precedence constraints. A similar argument to the one given in the proof of Lemma A.1 proves that $P$ never drives more than $\text{capa}$ clients at the same time and that $P$ satisfies the cost constraint. Finally, $P$ satisfies exactly $S = \frac{k \cdot (k - 1)}{2} + \sum_{i=1}^{k-1} d_i$ clients. \qed

\begin{lemma}
The route of a feasible taxi contains exactly one node in each sublayer and all the nodes of $X$.
\end{lemma}

\begin{proof}
As every sublayer $W_i^j$ is either linked to the next sublayer or connected to $W_{i+1}$ with the path $X_i \cup X_i'$, there is no path connecting two nodes of $W_i^j$. Thus, there is at most one node of $W_i^j$ is a path of $H$.

The taxi must go through at least one arc of cost 1, because, for every client, there is such an arc separating its origin to its destination. Thus, by Lemma A.1, it must satisfy at least one client from $W_i^k$. Consequently, again by Lemma A.1, it goes through every arc $(x_i^d, x_i^l)$ for $l \in [i; k - 1]$ and every node of $X$. Thus, again by Lemma A.1, the route of the taxi contains one node per sublayer. \qed

\begin{lemma}
If there is a feasible taxi for $J$ satisfying $S$ clients, there is a clique $C$ of size $k$ in $G$.
\end{lemma}

\begin{proof}
We now assume that there is a taxi $P$ satisfying $S$ clients. Let $C$ be the subgraph of $G$ induced by the set of edges $\{(u, v) \in E | w_u^i \in P \}$. Note that $w_u^i \in P \iff w_v^i \in P$ because $P$ satisfies the precedence constraint. By Lemma A.3, there is in $P$ exactly one node per sublayer and $P$ contains all the
nodes of $X$. As a consequence, for each $i < j$, there are at least one node $u_i \in V_i$ and one node $u_j \in V_j$ such that the client $c_{ui}$ is satisfied, thus, such that the edge $\{u_i, u_j\} \in C$. In addition, for each $i \leq k$, $|V_i \cap C| \geq 1$. By proving that $|V_i \cap C| = 1$ for all $i$, we prove that $C$ is a clique of size $k$ of $G$.

If, for some $i$, $|V_i \cap C| > 1$, there would be two nodes $u_1 \neq u_2 \in V_i \cap C$ and two other nodes $v_1, v_2$ such that $\{u_1, v_1\} \in C$ and $\{u_2, v_2\} \in C$. We assume that $v_1 \in V_{j_1}$, $v_2 \in V_{j_2}$ and $i < j_1 \leq j_2$. Every other case can be similarly proven. There are two nodes $w_1 = w_{u_1}^v \in W_i^j \cap P$ and $w_2 = w_{u_2}^v \in W_i^j \cap P$. By construction, there is a path in $H$ from $w_1$ to $w_2$ if and only if $u_1 = u_2$. As $w_1$ and $w_2$ belong to the path $P$, we deduce that $u_1 = u_2$ and that $|V_i \cap C| = 1$. And this conclude the proof.

**Hardness results.** Lemma A.3 proves that any feasible solution satisfies exactly $S$ clients and any taxi satisfies all the clients of $X$. Thus there cannot be two taxis in a feasible solution. Consequently, in that instance, an optimal solution of the problems max-1-DARP-M and max-DARP-M satisfies $S$ clients if and only if the answer to the problems max-1-DARP-M = YES, max-1-DARP-M and 1-DARP-M is YES. Otherwise, no client can be satisfied.

Lemma A.2 and A.4 proves then Theorem 3.3.

**Appendix B. Proof of the correctness of Algorithm 1**

This part is dedicated to proof the correctness of Algorithm 1. The key idea is to prove that any mapping of $P(w)$, for some node $w = (u, t, S, \kappa)$, corresponds to the part of a taxi from the first origin of its route to $u$, hereinafter called a partial taxi.

**Definition 6.** For every node $w = (u, t, S, \kappa) \in S(I)$, we define the set $pP(w)$ of partial taxis of $w$ as the set of paths $P$ in $G$ such that:

(i) $P$ starts at an origin $v_i$, for some client $i$, and ends at $u$

(ii) the capacity constraint is satisfied;

(iii) the time constraint is satisfied;

(iv) $S$ is the set $\{i | v_i \in P$ and $v_i' \notin P\}$ and $\kappa$ is the value of $|\{i | v_i \in P\}|$.

(v) if $v_i' \in P$, then the precedence and the cost constraints are satisfied for the client $i$;

(vi) if $i \in S$, the cost $\omega(i, P)$ paid by the client $i$ from $v_i$ to $u$ in $P$ is less than $\alpha \cdot \omega(v_i, v_i')$;

**Remark 6.** If $P$ is a taxi starting at $v_i$, then any subpath of $P$ starting at $v_i$ is a partial taxi. However, there exists partial taxis such that no valid taxi contains them.
Lemma B.1. Let \( w = (u, t, S, \kappa) \in S(I) \). We assume \( p \in P(w) \) is mapping that was just added at Line 14. Let \( P \) be the result of the BUILD function on \( w \) and \( p \), then \( P \in pP(w) \) and, for each \( i \in S \), \( p(i) = \omega(i, P) \).

Proof. Let \( L' \) be the list starting with the nodes of \( \{ w(v_i, t, \{ i \}, 1) | i \in [1;n], t \in [b_i, e_i] \} \) and ending with the list \( L \) defined at Line 6 of Algorithm 1. Note that any node \( w \) of \( \{ w(v_i, t, \{ i \}, 1) | i \in [1;n], t \in [b_i, e_i] \} \) has no predecessor (otherwise, let \( w^{-} = w(u^{-}, S^{-}, \kappa^{-}) \) be that predecessor, then, according to Definition 2, by the Rule 4 an arc of \( S(I) \) must satisfy, \( S^{-} = \emptyset \) and this is not compatible with Rule 1). As a consequence, \( L' \) is a topological ordering of \( S(I) \).

We prove the lemma by induction on the index of \( w \) in \( L' \).

**Basis:** We first prove the lemma for the nodes of \( \{ w(v_i, t, \{ i \}, 1) | i \in [1;n], t \in [b_i, e_i] \} \). Let \( w = w(v_j, t_j, \{ j \}, 1) \) be such a node. The set of mappings of \( w \) is initialized at Line 2 of Algorithm 1. The only mapping in \( P(w) \) is \( p_j \), the mapping associating 0 to the client \( j \). By Definition of \( pP(w) \), a partial taxi \( P \) of that set ends in \( v_j \) and satisfies \( \{ i | v_i \in P \} = \{ j \} \) and \( \{ i | v_i \in P \} = 1 \) by (i) and (iv). Thus, for all \( i \neq j, v'_i \in P \) otherwise, by (v), \( v_i \in P \) and this would be a contradiction with the fact that \( \{ i | v_i \in P \} = 1 \). Consequently, \( pP(w) \) contains only one partial taxi \( P = \{ v_j \} \). In that taxi, the client \( j \) pays 0. The lemma is then proved for \( w \).

**Inductive Step:** Let \( w = w(u, t, S, \kappa) \in L = L' \setminus \{ w(v_i, t, \{ i \}, 1) | i \in [1;n], t \in [b_i, e_i] \} \). We now assume that the lemma is true for every node before \( w \) in \( L' \).

Without loss of generality, we assume \( u \) is the origin \( v_j \) of the client \( j \).

Let \( p \) be a mapping of \( P(w) \), this mapping is added at Line 14 of Algorithm 1. Consequently, there is a predecessor \( w^{-} = (u^{-}, t^{-}, S^{-}, \kappa^{-}) \) of \( w \) and a mapping \( p^{-} \in P(w^{-}) \) such that \( (p, w^{-}, p^{-}) \in P(w^{-}, w) \) at Line 11. By Definition 2, as \( u \) is the origin of the client \( j \), \( S = S^{-} \cup \{ j \} \). The SUBMAP function is called at Line 10 of Algorithm 1. In that function, when \( p_1 = p^{-} \), the current iteration is not stopped at Line 9 of Algorithm 2, otherwise \( (p, w^{-}, p^{-}) \) would not be returned in \( P(w^{-}, w) \). Consequently, \( p(j) = 0 \) and, for each client \( i \in S^{-} \),

\[
p(i) = p^{-}(i) + \frac{\omega(u^{-}, v_j)}{|S^{-}|} \leq \alpha \cdot \omega(v_i, v'_i) \quad (B.1)
\]

Note that the value of \( \text{pred}(p^{-}) \) is never changed after Line 15 of Algorithm 1: if we call the BUILD function with \( p^{-} \) and \( w^{-} \) just after \( p^{-} \) is added to \( P(w^{-}) \) or if we call it later, the result is the same. By the inductive hypothesis, that function returns a partial taxi \( P^{-} \in pP(w^{-}) \) such that, for each \( i \in S^{-}, p^{-}(i) = \omega(v_i, P) \).

If we call BUILD after \( p \) is added to \( P(w) \), as \( \text{pred}(p) \) is set to \( (w^{-}, p^{-}) \), the result \( P \) is the path \( P^{-} \) to which we add the node \( v_j \). We now prove \( P \in pP(w) \).

- (i) is obviously proved for the path \( P \).
- As \( P^{-} \in pP(w^{-}) \), the capacity constraint is satisfied from the first node of \( P \) to \( v^{-} \) by (ii). By (iv), there are \( |S^{-}| \) clients in the taxi when it leaves.
Theorem B.1. Algorithm 1 returns an optimal solution for $\mathcal{I}$. By Definition 2, since the arc $(w^-,w)$ exists in $\mathcal{I}$ and since $u$ is an origin node, $|\mathcal{S}^-| \leq \text{capa} - 1$. Thus, there are at most $\text{capa}$ clients in the taxi when it leaves $v_j$ and (ii) is proved for $P$.

- The time constraint is satisfied for $P^-$. The taxi leaves $u^-$ at time $t^-$ and reaches $u$ at time $t^- + t(u^-,u)$. By (iii) Definition 2, $t$ belongs to the time windows associated with $u$ and, since the arc $(w^-,w)$ exists in $\mathcal{S}(\mathcal{I})$, $t = t^- + t(u^-,u)$. Consequently, (iii) is proved for $P$.

- $S = S^- \cup \{j\} = \{i \mid v_i \in P^- \text{ and } v'_j \notin P^-\} \cup \{j\}$ and $\kappa^- = |\{i \mid v_i \in P^-\}|$ by (iv). In $G$, there is no path from $v'_j$ to $v_j$, thus $v'_j \notin P^-$. Consequently, $S = \{i \mid v_i \in P \text{ and } v'_j \notin P\}$. Moreover, again by Definition 2, since the arc $(w^-,w)$ exists in $\mathcal{S}(\mathcal{I})$ and since $u$ is an origin node, $\kappa = \kappa^- + 1 = |\{i \mid v_i \in P^-\}|$. Consequently, (iv) is proved for $P$.

- $u$ is an origin node, then, as (v) is true for $P^-$, it is also true for $P$.

- The cost $\omega(i,P)$ paid by any client $i \in S^-$ in the path $P$ from $v_i$ to $v_j$ is $\omega(i,P^-) + \frac{\omega(u^-,v'_j)}{|\mathcal{S}^-|}$. By the inductive hypothesis, $\omega(i,P^-) = p^-(i)$. Thus, $\omega(i,P) = p^-(i) + \frac{\omega(u^-,v'_j)}{|\mathcal{S}^-|} = p(i) \leq \alpha \cdot \omega(v_i,v'_j)$ by Equation (B.1). The cost $\omega(j,P)$ paid by the client $j$ is 0, thus $\omega(j,P) = p(j) \leq \alpha \cdot \omega(v_j,v'_j)$. Consequently, (vi) is proved for the path $P$.

As a consequence, $P$ belongs to $pP(w)$ and, for each client $i \in S$, $p(i) = \omega(i,P)$. Lemma B.1 is shown for $w$. By induction, Lemma B.1 is proved.

**Lemma B.2.** For every node $w = (u,t,S,\kappa) \in \mathcal{S}(\mathcal{I})$, for each partial taxi $P \in pP(w)$, there is a mapping $p \in \mathcal{P}(w)$ such that, for each $i \in S$, $p(i) \leq \omega(i,P)$.

**Proof.** This proof is similar to the one of Lemma B.1. We do it by induction on the same list $L'$. The basis is exactly the same in the two proofs.

For the inductive step, a converse argument to the inductive step of Lemma B.1 proves that there is a mapping $p$ built with the SUBMAP function such that for each client $i \in S$, $p(i) = \omega(i,P)$. When, Algorithm 1 reaches Line 14, either there is a mapping $p' \leq p$ and, for each client $i \in S$, $p'(i) \leq p(i) = \omega(i,P)$ or no such mapping exists and $p$ is added to $\mathcal{P}(w)$. Lemma B.2 is shown for $w$ and by induction, Lemma B.2 is proved.

**Theorem B.1.** Algorithm 1 returns an optimal solution for $\mathcal{I}$.

**Proof.** We prove that Lines 17 and 20 returns either no solution if no solution exists or an optimal solution.

If, for some $w = w(v'_j,t,\emptyset,\emptyset,\kappa) \in T$, there is no mapping in $\mathcal{P}(w)$, then, by Lemma B.2, there is no valid taxi from any origin to $v'_j$ in $G$. If $T$ is empty, at Line 17, there is no solution and Algorithm 1 correctly returns no solution.

If such a mapping exists, by Lemma B.1, the function BUILD at Line 20 returns a path $P \in pP(\tau)$. As $\{i \mid v_i \in P \text{ and } v'_j \notin P\} = \emptyset$, thus every client of $P$ satisfies the precedence and the cost constraints: $P$ is a valid taxi. In
addition, $P$ satisfies $|\{i \mid v_i \in P\}| = \kappa$ clients. By definition of $\tau$, $P$ is an optimal solution.
