Abstract—In this paper, we first consider a simple Bayesian fusion problem in a matrix Lie group, and propose to tackle it using the unscented transform. The method is then leveraged to derive two simple alternative unscented Kalman filters on Lie groups, for both cases of noisy partial measurements of the state, and full state noisy measurements of the state on the group. The general method is applied to a robot localization problem, and results based on experimental data combined with extensive Monte-Carlo simulations at various noise levels illustrate the superiority of the approach over the standard UKF.

Keywords—Lie groups, unscented Kalman filter, robot localization.

I. INTRODUCTION

The problem of robot localization (and mapping) based on the fusion of various sensors has long been an important field. With the advent of probabilistic robotics methods within the field of mobile robotics, the role of accurate statistics for localization (and mapping) has been increasingly recognized. The Unscented Kalman Filter (UKF) introduced by roboticists [1,2] has become prevalent as an alternative to the Extended Kalman Filter (EKF) that may improve estimation in various cases and spares the practitioner the computation of Jacobians. Besides, there has been various recent works that have evidenced the fact that the Lie group structure of the configuration space $SE(3)$ plays a prominent role in probabilistic robotics, see [3]–[9]. It has also been shown recently that a Lie group underlies the state space in SLAM, and that using a (Lie group) Invariant EKF [6], the consistency issues of the EKF-SLAM can be fixed [10].

In this paper we consider systems whose state is an unimodular matrix Lie group. Using exponential coordinates to define Gaussians on the group, we derive a Lie group version of the unscented Kalman filter. We consider two distinct problems: the problem of noisy partial measurement of the state that live in a vector space, and the problem of full state noisy measurement which is to be treated slightly differently, as the measurement then lives in the Lie group. For each type of measurement, the proposed UKF on Lie Groups consists of two different variants: one based on left multiplications, and the other based on right multiplications. It turns out the variant that works best depends on the problem at hand, and both should be tested when one has no clear insight on which should be the best.

A. Links and Differences with Previous Literature

The original UKF and its square-root implementation [11] have been extensively adapted and used for attitude estimation. The filter does not fully use the Lie group structure of the state space, notably the Lie exponential map, but rather takes advantage of the quaternion representation of $SO(3)$, which does not carry over to general Lie groups. Recent works have also advocated the use of particular probability densities on $SO(3)$, the so-called Fisher distributions, as an interesting alternative to the Lie exponential coordinates of [3], and have brought them to bear for unscented attitude estimation [13].

Another line of research uses the unscented transform on Lie groups and Lie exponential coordinates to derive uncertainty ellipsoids that are proved to contain with certainty the state, when faced with bounded sensor errors, see [14,15]. [16,17] also introduced an Invariant UKF, as an UKF capable of taking into account the symmetries of the system’s equations, for state spaces that are generally not Lie groups.

Regarding $SE(3)$ and more general Lie groups, one can essentially follow two slightly different routes to describe Gaussians in exponential coordinates. The first consists in directly defining a density on the group, that can be referred to as concentrated Gaussian, as in [18,19]. Those distributions were recently used for extended Kalman filtering on Lie groups by [20]. The second one consists in assuming the distribution to be normal in the Lie algebra, and then to map it to the group through the exponential map, as advocated by [5] for robotics applications, and at the heart of the Invariant EKF of [6,21]. In the present paper, we follow this second method. This yields a propagation step of the UKF that is identical to the method of [5] to compound poses. However, [5] does not treat Bayesian estimation on $SE(3)$, which is necessary to update the state of the UKF when given a novel measurement.

The very recent paper [22] also proposes an UKF on the Lie group $SE(3)$ for a navigation application. Beyond the fact it is only concerned with $SE(3)$ whereas the present paper deals with general Lie groups, the method is different since it uses concentrated Gaussians on Lie groups of [18]. As a result, the method can be related to the general unscented Kalman filtering on manifolds of [23], where the sigma points are mapped onto the manifold, and then the logarithm map is used to map them back in some tangent space where averages and covariances can be computed, whereas the sigma points in our method below live in a vector space, and are never mapped onto the group itself (regarding partial measurements). Last but not least, the method of [22] is based on left multiplications, notably on the left-invariant connection of $SE(3)$, whereas, as emphasized in the present paper, right multiplications allow defining an alternative UKF. This is important, as simulations of Section V-D indicate the right multiplications based UKF precisely suits best measurements in the body frame, such as those considered in [22].
B. Paper’s Organization and Contributions

The paper is divided into six sections as follows. Section II contains mathematical preliminaries. Each of the following three sections constitutes a contribution of the present paper. In Section III, we design different Bayesian estimators on Lie groups based on the unscented transform for various kinds of measurements. The method is applied in Section IV to derive two UKF on Lie groups. Section V considers 2D robot localization problem that uses experimental data, and illustrates the superiority of the proposed UKF over the standard UKF and the Invariant EKF.

II. MATHEMATICAL PRELIMINARIES

A. Lie Groups

In this section we recall the definitions and basic properties of unimodular Lie groups, Lie algebra and random variables on Lie groups. A matrix Lie group \( G \subset \mathbb{R}^{N \times N} \) is a set of square invertible matrices that is a group, i.e., the following properties

\[ I \in G; \forall X \in G, X^{-1} \in G; \forall X_1, X_2 \in G, X_1X_2 \in G \quad (1) \]

hold. Locally about the identity matrix \( I \), the group \( G \) can be identified with an Euclidean space \( \mathbb{R}^q \) using the matrix exponential map \( \exp \), where \( q = \dim G \). Indeed, to any \( \xi \in \mathbb{R}^q \) one can associate a matrix \( \chi^\xi \) of the tangent space of \( G \) at \( I \), called the Lie algebra \( \mathfrak{g} \). We then define the exponential map \( \exp : \mathbb{R}^q \to G \) for Lie groups as

\[ \exp (\xi) = \exp_m (\chi^\xi), \]

(2)

Locally, it is a bijection, and one can define the Lie logarithm map \( \log : G \to \mathbb{R}^q \) as the exponential inverse, leading to

\[ \log (\exp (\xi)) = \xi. \]

(3)

B. Uncertainties on Lie Groups

To define random variables on Lie groups, we cannot apply the usual approach of additive noise for \( X_1, X_2 \in G \) as \( G \) is not a vector space, i.e., generally \( X_1 + X_2 \notin G \) does not hold. In contrast, we adopt the framework of [5], see also [6,21], which is slightly different from the pioneering approach of [3,24]. Indeed, we define the probability distribution \( X \sim \mathcal{N}_L (\bar{X}, \mathbf{P}) \) for the random variable \( X \in G \) as

\[ X = \bar{X} \exp (\xi), \quad \xi \sim \mathcal{N} (0, \mathbf{P}), \]

(4)

where \( \mathcal{N} (\ldots) \) is the classical Gaussian distribution in Euclidean space and \( \mathbf{P} \in \mathbb{R}^{q \times q} \) is a covariance matrix. In the sequel, we will refer to (4) as the left-equivariant Gaussian distribution on \( G \), due to its compatibility with left multiplications. In (4), the noise-free quantity \( \bar{X} \) is viewed as the mean, and the dispersion arises through left multiplication with the exponential of a Gaussian random variable. Similarly, the distribution \( X \sim \mathcal{N}_R (\bar{X}, \mathbf{P}) \) can be defined through right multiplication as

\[ X = \exp (\xi) \bar{X}, \quad \xi \sim \mathcal{N} (0, \mathbf{P}). \]

(5)

We stress that we have defined these probability density functions directly in the vector space \( \mathbb{R}^q \) such that both \( \mathcal{N}_L (\ldots) \) and \( \mathcal{N}_R (\ldots) \) are not Gaussian distributions.

III. BAYESIAN ESTIMATION ON LIE GROUPS USING THE UNSCENTED TRANSFORM

Consider a random variable \( X \in G \) with prior probability distribution \( p (X) \). Suppose we obtain some additional information about \( X \) through a measurement \( y \). The goal of Bayesian estimation is to compute an estimate of the posterior distribution \( p(X|y) \). In this section, we derive various algorithms for various types of measurements.

A. Partial Measurement with Left-equivariant Prior Uncertainty \( (4) \)

Consider a generic vector measurement of the form

\[ y = h (X) + v, \]

(6)

where \( h(\cdot) : G \to \mathbb{R}^k \) represents the observation function and \( v \sim \mathcal{N} (\mathbf{0}, \mathbf{R}) \) is a Gaussian random noise in \( \mathbb{R}^k \) with known characteristics. The problem of Bayesian estimation we consider is as follows:

1) consider the prior distribution follows (4), i.e.,

\[ p(X) \sim \mathcal{N}_L (\bar{X}, \mathbf{P}), \]

(7)

with known parameters \( \bar{X} \) and \( \mathbf{P} \);

2) assume one measurement \( y \) given by (6) is available;

3) approximate the posterior distribution as

\[ p(X|y) \approx \mathcal{N}_L (\bar{X}^+, \mathbf{P}^+), \]

(8)

and compute the estimates of both posterior parameters \( \bar{X}^+ \) and \( \mathbf{P}^+ \).

To attack this problem, one can resort the unscented transform of [1]. First, and contrarily to [22], we use the fact that the problem is amenable to nonlinear filtering in a vector space, as we have \( \xi \sim \mathcal{N} (0, \mathbf{P}) \) with nonlinear measurement (6). The UKF thus allows us to approximate the posterior \( p(\xi|y) \) for \( \xi \) as follows: we compute a finite number of samples \( \alpha_j = [\xi_j^T \mathbf{v}_j^T] \), \( j = 0, \ldots, 2l \), with \( l = q + k \), and then pass each of these so-called sigma points through the measurement function

\[ y_j = h (\bar{X} \exp (\xi_j)) + \mathbf{v}_j, \quad j = 0, \ldots, 2l, \]

(9)

and we then compute successively the measurement mean \( \bar{y} \), the measurement covariance \( \mathbf{P}_{y\bar{y}} \) and the cross-covariance \( \mathbf{P}_{\xi y} \). We thus approximate the posterior for \( \xi \) in \( \mathbb{R}^q \) as

\[ p(\xi|y) \sim \mathcal{N} (\bar{\xi}, \mathbf{P}^+), \]

(10)

\[ \left[ \begin{array}{c} \bar{\xi} \\ \bar{y} \end{array} \right] = \mathbf{P}_{\xi y} \mathbf{P}_{y\bar{y}}^{-1} (y - \bar{y}) \]

(11)

\[ \mathbf{P}^+ = \mathbf{P} - \mathbf{P}_{\xi y} (\mathbf{P}_{\xi y} \mathbf{P}_{y\bar{y}}^{-1})^T. \]

(12)

The unscented approximation to the posterior \( p(\xi|y) \) is thus a distribution of a Gaussian \( \xi + \xi^+ \) with \( \xi^+ \sim \mathcal{N} (0, \mathbf{P}^+) \). Back to the Lie group, this means we approximate the posterior distribution through the variable \( \bar{X} \exp (\xi + \xi^+) \). The Baker-Campbell-Hausdorff (BCH) formula provides a simple (first-order) approximation as \( \exp (\xi + \xi^+) \approx \exp (\xi) \exp (\xi^+) \). This readily yields an approximate \( \bar{X}^+ \exp (\xi^+) \) to the posterior of the form (4), with

\[ \bar{X}^+ = \bar{X} \exp (\xi), \quad \xi^+ \sim \mathcal{N} (0, \mathbf{P}^+). \]

(13)
that concludes the Bayesian estimation, which is summarized in Algorithm 1.1.

B. Partial Measurement with Right-equivariant Prior Uncertainty (5)

In the latter subsection, we considered that both the prior and posterior follow the distribution of the form (4). If we assume the prior has the form (5), then it is natural to assume that the posterior is also of the form (5). In this case, we substitute the computed measurements \( y_j, \ j = 0, \ldots, 2l \) in (9) as

\[
y_j = h(\exp(\xi_j) \bar{X}) + v_j \tag{14}
\]

and the posterior mean (13) as

\[
\bar{X}^+ = \exp(\xi) \bar{X}. \tag{15}
\]

The difference between both methods may prove non-negligible as will be illustrated in Section V-D.

C. Full State Measurement: Bayesian Pose Fusion

Assume we have a prior of the form \( p(X) \sim N_\lambda(\bar{X}, P) \) and a measurement of the type

\[
Y = \chi V, \tag{16}
\]

where \( \chi \) is the true state and \( V \) a noise of the form

\[
V = \exp(v), \ \ v \sim N(0, R). \tag{17}
\]

This kind of measurement happens for instance in \( \text{SE}(3) \), when an algorithm is used to compute a pose directly from perception sensors such as, stereo images, or scan matching algorithms with point clouds, and when a covariance can be associated to the computed pose, see e.g., [26].

1) Proposed Method: in this case, we need to approximate the posterior \( p(X|Y) \sim N_\lambda(\bar{X}^+, P^+) \), which appears to be nontrivial. Indeed, in (16), \( \lambda \) is a matrix measurement, and this matrix belongs to \( G \) which is not a vector space, so both the definition and the computation of the covariance of \( Y \) is not straightforward. For such measurement, we propose using the logarithm map to obtain

\[
y = \log(\bar{X}^{-1}Y) = \log(\bar{X}^{-1}\chi V). \tag{18}
\]

Thanks to this transformation, the computed transformed output \( y \) belongs to vector space \( \mathbb{R}^n \), and we can then apply the proposed Bayesian estimation of Section III-A, with

\[
y_j = \log(\exp(\xi_j) \exp(v_j)), \ \ j = 0, \ldots, 2l, \tag{20}
\]

to obtain the posterior \( p(X|Y) \sim N_\lambda(\bar{X}^+, P^+) \).

2) Fusion with Right-equivariant Prior Uncertainty (5): assume that we have a prior of the form (5), or by symmetry (inverting all quantities), that we have a left prior of the form (4) but with an output of the form \( Y = VX \). We then propose to write \( Y = VX \exp(\xi) = \bar{X}X^{-1}V \) \( \exp(\xi) = \bar{X}X^{-1} \exp(v) \) \( \exp(\xi) = 1 \) \( \exp(\text{Ad}_{\bar{X}^{-1}} \chi v) \exp(\xi) \) where \( \text{Ad} \) is the adjoint operator of the group. We can thus compute the modified output

\[
y = \log(\bar{X}^{-1}Y) = \log(\exp(\text{Ad}_{\bar{X}^{-1}} \chi v) \exp(\xi)). \tag{21}
\]

Thanks to this transformation, we recover a measurement similar to (19), but with noise having covariance matrix

\[
\text{Ad}_{\bar{X}^{-1}} R(\text{Ad}_{\bar{X}^{-1}}) \tag{21}
\]

The method above can then be readily applied.

3) Rationale for the Transformation of the Output: consider output (16). One could argue that \( y = \log(Y) \) is already a vector, and a function of \( \xi \) so that a UKF estimate can readily be built along the lines of Section III-A. However, when \( \bar{X} \) is far from the identity, a large distortion is induced by the logarithm map. But \( \chi \) and \( v \) being moderate zero-centered noises in applications, we have using BCH formula

\[
\log(\exp(\xi) V) = \xi + V + o(||\xi||, ||V||). \tag{21}
\]

Thus up to first order terms the transformed output \( y \) of (19) is a true Gaussian, and the posterior output by the UKF will be very close to the true one, no matter \( \bar{X} \), whereas \( \log(Y) \) can be dramatically non-Gaussian, preventing the UKF estimate from being accurate.

4) Links with the Pose Fusion Method of [5]: [5] proposes an algorithm to fuse various measurements of the form (16). With two measurements only, it boils down to estimating an unknown group element \( \bar{X} \) from measurements \( Y_1 = \bar{X} \exp(v_1) \) and \( Y_2 = \bar{X} \exp(v_2) \), where \( v_1 \) and \( v_2 \) are centered Gaussians in \( \mathbb{R}^q \) with known covariance matrices. In the Euclidean case, the corresponding problem is to estimate some quantity \( \mu \) from two noisy measurements \( y_1 = \mu + n_1 \) and \( y_2 = \mu + n_2 \) where \( n_1 \) and \( n_2 \) are centered Gaussian noises with known covariance matrices. This is a classical estimation problem, that is optimally handled through

---

\[1\] According to [1,25], we set unscented transform parameters to \( \kappa = 0 \) and \( \beta = 2 \). \( \kappa \) keeps a free-parameter chosen by the practitioner, which must be small \( (\kappa = 10^{-3}) \) in our applications. The operator \( \text{diag}(\lambda) \) put in a block diagonal matrix its arguments in Step 3, the square-root matrix in step 4 is obtained from Choleski decomposition and \( \text{col}(P) \) represents the \( j \)-th column of \( P \).
least squares, and does not imply the Kalman update equation (Gaussian conditioning). The problem considered in the present section is quite different, since it deals with Bayesian fusion of poses, which implies conditional probabilities. In our case $\chi$ is known, and we want to refine our statistics on the random quantity $\mathcal{X} \exp (\xi)$, given that we have measured, e.g., $\mathcal{Y} = \mathcal{X} \exp (\xi) \exp (\nu)$.

IV. APPLICATION TO UNSCENTED KALMAN FILTERING ON LIE GROUPS

A. System Model

In the rest of this paper we consider a discrete dynamic system of the form

$$\chi_n = \chi_{n-1} \exp (\omega_n + w_n),$$

(22)

where the state $\chi_n$ lives in $G$, $\omega_n$ is a known input variable and $w_n \sim \mathcal{N}(0, Q_n)$ is a white Gaussian noise. We design two different filters for generic discrete measurements of the form

$$\mathcal{Y}_n = \chi_n \exp (v_n),$$

(23)

where $v_n \sim \mathcal{N}(v_n, R_n)$.

B. Unscented Kalman Filter on Lie Groups with Left-equivariant Uncertainties (4)

For the model (22) with measurements given by (23), we can model the state as $\chi_n \sim \mathcal{N}_{\ell}(\bar{\chi}_n, P_n)$, that is, using the left-equivariant formulation (4) of the uncertainties. The goal is to compute both estimates of $\bar{\chi}_n$ and $P_n$ at each time. The proposed Left-UKF-LG acts in two steps: propagation and update. We now develop these two steps.

1) Propagation: starting from the prior distribution

$$p(\mathcal{X}_{n-1}) \sim \mathcal{N}_{\ell} (\bar{\chi}_{n-1}, P_{n-1}),$$

(25)

with $\bar{\chi}_{n-1}$ and $P_{n-1}$ known, we seek to approximate the propagated state distribution

$$p(\mathcal{X}_n|\mathcal{X}_{n-1}) \sim \mathcal{N}_{\ell} (\bar{\chi}_n, P_n),$$

(26)

i.e., we search to compute both $\bar{\chi}_n$ and $P_n$.

This step can be viewed as a straightforward application of the method of [5] to compound poses using the unscented transform. The state mean estimate is propagated using the unnoisy state model, leading to

$$\bar{\chi}_n = \bar{\chi}_{n-1} \Omega_n,$$

(27)

with $\Omega_n = \exp (\omega_n)$. According to [5] this approximation of the mean is valid up to the second order, so there is no need to compute it through the unscented transform (the calculations of [5] deal with $SE(3)$, but we have checked they carry over to the general Lie group case). We then resort to the unscented transform to determine the covariance $P_n$ by first approximating the joint Gaussian variable using a finite number of samples $\xi_j, w_j, j = 1, \ldots, 4q$. To propagate these samples, we inject (4) in (22) as

$$\bar{\chi}_n \exp (\xi_n) = \bar{\chi}_{n-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(28)

which simplifies as follows

$$\exp(\xi_n) = \bar{\chi}_{n}^{-1} \bar{\chi}_{n-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(29)

$$\exp(\xi_n) = \Omega_n^{-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(30)

by use of (27). Algorithm 2 summarizes this propagation step.

2) Update: this step consists in incorporating the information coming from the measurement. As concerns measurements $y_n$ of the form (23), it boils down to a Bayesian estimation problem, where we search to approximate the posterior probability distribution as

$$p(\chi_n|y_n, y_{n-1}, \ldots, y_1) \sim \mathcal{N}_{\ell} (\bar{\chi}_n^+, P_n^+),$$

(31)

with available prior

$$p(\chi_n|y_{n-1}, \ldots, y_1) \sim \mathcal{N}_{\ell} (\bar{\chi}_n, P_n).$$

(32)

We apply for the update estimates directly Bayesian estimation as developed in Section III-A, yielding both $\bar{\chi}_n^+$ and $P_n^+$.

To update the filter with a measurement of the type (24), we first approximating the joint Gaussian variable using a finite number of samples $\xi_j, w_j, j = 1, \ldots, 4q$. To propagate these samples, we inject (4) in (22) as

$$\bar{\chi}_n \exp (\xi_n) = \bar{\chi}_{n-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(28)

which simplifies as follows

$$\exp(\xi_n) = \bar{\chi}_{n}^{-1} \bar{\chi}_{n-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(29)

$$\exp(\xi_n) = \Omega_n^{-1} \exp (\xi_{n-1}) \exp (\omega_n + w_n),$$

(30)

by use of (27). Algorithm 2 summarizes this propagation step.

C. Unscented Kalman Filter on Lie Groups with Right-equivariant Uncertainties (5)

For the model (22) with measurements given by (23), we can model the state as $\chi_n \sim \mathcal{N}_{\ell}(\bar{\chi}_n, P_n)$, that is, using the right-equivariant formulation (5) of the uncertainties. The filter is defined in an analogous way to the previous Section IV-B. The resulting filter is yet different, and we call it Right-UKF-LG.
The equation governing the noisy system evolution then becomes

\[ x_n = x_{n-1} \exp (\omega_n + w_n), \]  

where \( x_n \) and \( \omega_n \) represent, respectively, the difference in position and the angular velocity \( \omega_n \in \mathbb{R} \), e.g., by a differential odometer or a gyrometer. Taking into account the possible noise in the measurements, we get the discrete model

\[
\begin{align*}
\theta_n &= \theta_{n-1} + \omega_n + w_n^\theta, \\
x_n^1 &= x_{n-1}^1 + \cos (\theta_n) (u_n + w_n^1) - \sin (\theta_n) w_n^{tr}, \\
x_n^2 &= x_{n-1}^2 + \sin (\theta_n) (u_n + w_n^1) + \cos (\theta_n) w_n^{tr},
\end{align*}
\]

where \( w_n^\theta, w_n^1 \) and \( w_n^{tr} \) represent, respectively, the differential odometry error, the longitudinal odometry error and the transversal shift, whose introduction is thus physically motivated. We assume the vehicle obtains some noisy measurements of its position of the form

\[ \tilde{y}_n = x_n + \tilde{v}_n, \quad \tilde{v}_n \sim \mathcal{N} \left( 0, \begin{bmatrix} \sigma^2 & 0 \\ 0 & \sigma^2 \end{bmatrix} \right), \]

which typically models a GPS position in an outdoor application. The system can be embedded in the matrix Lie group \( G = SE(2) \) as explained in Appendix A, using \( X_n \) as the state, and

\[ \omega_n = \begin{bmatrix} \omega_n^1 \\ u_n \\ 0 \end{bmatrix} \quad \text{and} \quad w_n = \begin{bmatrix} w_n^\theta \\ w_n^1 \\ w_n^{tr} \end{bmatrix}. \]

The equation governing the noisy system evolution then becomes

\[ X_n = X_{n-1} \exp (\omega_n + w_n) \]  

and the observations have the equivalent form

\[ y_n = X_n \begin{bmatrix} 1 \\ 0 \end{bmatrix} + \tilde{v}_n \]

V. RESULTS FOR EXPERIMENTAL DATA

To demonstrate the performances of the proposed method, we first apply the proposed Left-UKF-LG to the following nonlinear standard model of the two-dimensional differential drive car [27], and compare it to various algorithms of the literature. The velocity \( u_n \in \mathbb{R} \) is given by an odometer and we measure the angular velocity \( \omega_n \in \mathbb{R} \), e.g., by a differential odometer or a gyrometer. Taking into account the possible noise in the measurements, we get the discrete model

\[ y_n = x_n + v_n \]

where \( y_n \) is the transversal shift, whose introduction is thus physically motivated. We assume the vehicle obtains some noisy measurements of its position of the form

\[ \tilde{y}_n = x_n + \tilde{v}_n, \quad \tilde{v}_n \sim \mathcal{N} \left( 0, \begin{bmatrix} \sigma^2 & 0 \\ 0 & \sigma^2 \end{bmatrix} \right), \]

which typically models a GPS position in an outdoor application. The system can be embedded in the matrix Lie group \( G = SE(2) \) as explained in Appendix A, using \( X_n \) as the state, and

\[ \omega_n = \begin{bmatrix} \omega_n^1 \\ u_n \\ 0 \end{bmatrix} \quad \text{and} \quad w_n = \begin{bmatrix} w_n^\theta \\ w_n^1 \\ w_n^{tr} \end{bmatrix}. \]

The equation governing the noisy system evolution then becomes

\[ X_n = X_{n-1} \exp (\omega_n + w_n) \]

and the observations have the equivalent form

\[ y_n = X_n \begin{bmatrix} 1 \\ 0 \end{bmatrix} + \tilde{v}_n \]

A. Experimental Setting

We then compare the various filters for the model described in Section V on real data obtained in an experiment conducted at the Centre for Robotics, MINES ParisTech. We used a so-called Wifibot, which is a small wheeled robot equipped with independent odometers on the left and right wheels, see Fig. 1. A set of seven highly precise cameras, the OptiTrack motion capture system, provide the reference trajectory (ground truth) \( \theta_n \) and \( x_n \) with sub-millimeter precision at a rate of 120 Hz. We display the experimental trajectory in Fig. 2, corresponding to a random motion of 45 seconds. From this trajectory, we can determine the odometry noise characteristics to parametrize correctly the covariance matrix \( Q_n \).

![Fig. 1: Testing arena with Wifibot robot in the foreground of the picture. We can also see two of the seven Optitrack cameras in the background.](image)

![Fig. 2: Ground truth trajectory starting from the position (0,0) and estimated trajectories with wrong initial positions. The noise is moderate to high (\( \sigma^2 = 10^{-3} \text{m}^2 \)). The standard UKF and EKF encounter serious difficulties at the beginning due to initial dispersion encoded in \( P_0 \).](image)
Fig. 3: Monte-Carlo average of the Root Mean Square Error on $(\theta_n)_{1 \leq n \leq N}$ over the whole trajectory, as a function of the noise measurement variance $\sigma^2$. Standard UKF and EKF achieve identical RMSE.

Fig. 4: Monte-Carlo average of the Root Mean Square Error on $(x_n)_{1 \leq n \leq N}$ over the whole trajectory, as a function of the noise measurement variance $\sigma^2$. Standard EKF and UKF achieve identical RMSE.

B. Results

To compare the proposed Left-UKF-LG2 with other methods for different levels of noise, we provide each filter with the raw odometer inputs $\omega_n$ and Wartificially add Gaussian noise to the ground truth position measurements to simulate noisy position measurements, delivered to the filter at a rate of 1 Hz. Initially, we set for the filters both incorrect heading $\dot{\theta}_0 \sim \mathcal{N}(0, (\pi/2)^2)$ and position $\bar{x}_0 \sim \mathcal{N}(0, 1/8)$, $\bar{x}_0^2 \sim \mathcal{N}(0, 1/8)$. We then run 500 Monte-Carlo simulations for different levels of measurement noise $\sigma^2 = \left[10^{-5}, 10^{-1}\right]$ m$^2$ and compare the (average) Root Mean Square Errors w.r.t. the ground truth over the whole trajectory. Results are displayed in figures Fig. 3 and Fig. 4.

C. Discussion

For this trajectory, Left-UKF-LG and IEKF provide best position estimates at low noise. Regarding the heading, IEKF is slightly better than Left-UKF-LG at low noise but Left-UKF-LG becomes the most efficient filter when noise is moderate. We thus see that the Left-UKF-LG takes advantage of both the geometry-based structure of the IEKF, and the robustness of the unscented method. The following points seem important to us:

- The problem at hand (33) can be treated without the Lie group machinery, using $x_n$ and $\theta_n$ as vector state variables. However, we see that embedding it into a Lie group framework yields more powerful variants of the Kalman filter (the IEKF and the Left-UKF-LG).
- One could think the standard UKF systematically performs better than the standard EKF, especially when the measurement noise is high, due to its second order properties. This is generally true, but not always, as evidenced by the considered experiment.
- On the other hand, it seems the Lie group counterpart of the UKF improves the Lie group counterpart of the EKF, that is, the IEKF.

D. Differences Between Left-UKF-LG and Right-UKF-LF

In the latter section, we focused on the comparison between Left-UKF-LG and some existing filters. We illustrate in this section that there may be discrepancies between the performances of Left-UKF-LG and Right-UKF-LF. To do so we still consider the system model (36) but with alternative measurements

\begin{align}
Y_n^j &= R(\theta_n) (x_n - p^j) + v_n^j, \quad j = 1, \ldots, J, \quad \text{where} \quad (38) \\
R(\theta_n) &= \begin{bmatrix} \cos(\theta_n) & -\sin(\theta_n) \\ \sin(\theta_n) & \cos(\theta_n) \end{bmatrix}, \quad (39)
\end{align}

which represent a range-and-bearing observation of a sequence of known features located at $p^j \in \mathbb{R}^2$ for $j = 1, \ldots, J$, and where we let $R(\theta)$ be the planar rotation of angle $\theta$. In our setting, we define $J = 3$ features $p^1 = [12]^T$, $p^2 = [-0.5 \ 0]^T$ and $p^3 = [0 \ 1]^T$. We then run 200 Monte-Carlo simulations for different levels of measurement noise.

---

2We similarly implemented the Right-UKF-LG but we show only Left-UKF-LG which is the most efficient for the measurement (34).
\[ \sigma^2 = [10^{-5}, 10^{-1}] m^2 \] and compared the Root Mean Square Error w.r.t. the ground truth. Results are displayed in figures Fig. 5 and Fig. 6. They clearly reveal that the Right-UKF-LG outperforms both Left-UKF-LG and UKF in this particular case. In the absence of further insight, we thus recommend to the practitioner to design, implement and compare both UKF-LG variants, and then select the most efficient of them.

VI. CONCLUSION

We presented in this paper different solutions to Bayesian estimation problems on matrix Lie groups based on the UKF methodology, when the measurements consist of noisy partial measurements of the state, or full state noisy measurements of the state. We then applied these estimators to derive an UKF on Lie groups that comes in two variants. Experimental data combined with extensive Monte-Carlo simulations at various measurement noise levels illustrated the systematic superiority of the approach over the standard UKF on a robot localization example. Future work involves applications to drone navigation and to SLAM.

ACKNOWLEDGMENT

The authors would like to thank Martin BARCZYK, Tony NOEL for their precious help with the experiments.

APPENDIX A

SPECIAL EUCLIDEAN 2D GROUP

The Special Euclidean 2D \( SE(2) \) group represents rigid transformations in 2D space and has \( q = 3 \) parameters: heading \( \theta \) and position \( x = [x^1, x^2]^T \). The elements \( X \in SE(2) \), \( \xi^\Lambda \in \xi \), are given, respectively, as

\[
X = \begin{bmatrix}
\cos(\theta) & -\sin(\theta) & x^1 \\
\sin(\theta) & \cos(\theta) & x^2 \\
0 & 0 & 1
\end{bmatrix}
\quad \text{and} \quad
\xi^\Lambda = \begin{bmatrix}
0 & -\xi^1 & \xi^2 \\
\xi^1 & 0 & \xi^3 \\
0 & 0 & 0
\end{bmatrix}.
\]

(40)

The exponential and logarithm maps are obtained as

\[
\exp(\xi) = \begin{bmatrix} R(\xi^1) & V_\xi \xi^2 \\
0 & 1 \end{bmatrix}, \quad \log(X) = \begin{bmatrix} V_X^{-1}X \\
0 \end{bmatrix},
\]

(41)

where \( R(\xi^1) \) is defined in (39),

\[
V_\xi = \frac{1}{\xi^1} \begin{bmatrix} \sin(\xi^1) & -1 + \cos(\xi^1) \\
1 - \cos(\xi^1) & \sin(\xi^1) \end{bmatrix}
\quad \text{and} \quad
V_X = \frac{1}{\theta} \begin{bmatrix} \sin(\theta) & -1 + \cos(\theta) \\
1 - \cos(\theta) & \sin(\theta) \end{bmatrix},
\]
