SiN_x and SiN_x:Tb³⁺ thin layers were deposited by reactive magnetron co-sputtering with the objective of optimizing the light management in Si solar cells. Those Si-based layers are developed to be compatible with the Si-PV technology. An efficient energy transfer between SiN_x matrix and terbium ions (Tb³⁺), enhancing this system absorption, has been demonstrated and optimized. The layer composition and microstructure as well as its optical properties have been analyzed with the aim of improving both its anti-reflective properties and its luminescence emission intensity. An optimized layer was obtained by co-sputtering of Si and Tb targets in a nitrogen rich atmosphere. The emission efficiency of the SiN_x:Tb³⁺ layer is compared to the one of previously optimized SiO_xN_y:Tb³⁺ layer. Finally we show how SiN_x:Tb³⁺ thin films may be integrated on top of Si solar cells and act simultaneously as a down-shifting layer and antireflective coating.

1. Introduction

Solar energy is one of the sustainable energies considered for the progressive replacement of fossil fuels in our society. However, to continuously reduce the cost per Watt, improving Solar Cell (SC) efficiency is essential. Despite Si-SC technology being currently the most used, it suffers from a low efficiency ranging from 12% to 20% depending on the quality level of the system. This low efficiency is mainly due to the energy mismatch between the solar spectrum and the Si bandgap. Indeed, only the photons with energy higher than the Si bandgap are absorbed by the SC. Moreover, the energy excess of those photons with respect to the bandgap energy is released into the matrix via transfer to phonons in a thermalization process. Consequently, an increase of 1 °C above 25 °C leads to a decrease of the cell efficiency by around 0.65% [1–3]. The rising temperature also leads to a faster aging of the cell. Another cause of the low efficiency limit is the fact that all the light received by the cell is not absorbed due to reflection of the incident light at the surface of the SC. Even while using light-trapping devices, Yablonovitch [4] demonstrated that a maximum achievable light path length enhancement of $4n^2$ may be attained (with n the refractive index of the bare SC).

As laboratory Si-SC efficiency is close its theoretical limit [5], one of the next steps for improving the single junction Si-SC efficiency consists in studying the management of the light within the SC. Some solutions

are already implemented on SC such as texturation or anti-reflective layers [5–7]. New solutions consisting in a frequency conversion of the light to adapt the solar spectrum to the cell bandgap are down-shifting [8,9] and down/up-conversion layers [8,10–14]. Those frequency conversions are usually achieved by using rare earth-doped matrices. The up-conversion layer concerns the photons transparent for the Si-SC and thus is placed at the bottom of the cell. The down-conversion or down-shifting layers are deposited on top of the solar cells to improve the use of the incoming photons with an energy higher than the Si bandgap. In a down-conversion (DC) layer, one UV photon is transformed in two IR photons having an energy just above the SC bandgap. Thus the number of photons used by the cell increases while the thermalization decreases. Whereas a down-shifting (DS) layer will absorb one UV photon and reemit a single photon with an energy above the SC bandgap. Thus the down-shifted photons wavelengths better match the spectral photo-absorptivity response of the Si-SC. In addition the thermalization process will take place in the DS layer instead of the SC. Thus by thermally isolating the DS layer from the SC, with transparent materials, the thermalization could be partially decoupled from the cell which reduces the entropy flow and may increase the cell efficiency as described by Landsberg efficiency [15]. A DS layer is composed of a matrix containing one rare earth ion whereas in a down-conversion layer, two or more rare earth ions are incorporated in the matrix. Many matrices and rare earth ions have been

studied in both cases [9,16–19].

The goal of our study consists in developing Si-based frequency conversion layers compatible with the Si-SC industry process in order to lower the production cost and increase the SC efficiency. Moreover, such DS- or DC-layer should be stable, which was not the case with most of the matrices studied. Indeed, they were either degraded during the SC processing or damaged by high energy photons during sun exposure [14]. In addition, some of those used materials were toxic because of the presence of fluorine [20] or of heavy metals such as cadmium [21], or lead [22]. Following this reasoning, various studies using a silicon oxynitride matrix, SiO_xN_y , doped with terbium ions (Tb^{3+}) have been carried out [23–25]. However, the presence of oxygen favors the rare earth clusters formation that is detrimental to an intense emission. Our study then focuses on the terbium-doped silicon nitride matrix, $\text{SiN}_x\text{:Tb}^{3+}$, such a system being free of oxygen to promote rare earth ions incorporation [26]. SiN_x has been chosen as host matrix since it is already used as anti-reflective layer on industrial Si-SC which is a way to develop new approach keeping a low production cost of the SC. Besides, such a host matrix should be an efficient sensitizer to the rare earth ions that have a weak absorption cross-section (below $2 \times 10^{-21} \text{ cm}^2$ [27]) in silicon based matrices. Consequently, such a host matrix should have a high absorption in the UV range as well as efficient sensitizing properties toward Tb^{3+} ions while keeping its anti-reflective properties.

In this paper we will describe the optimizations of the undoped SiN_x and $\text{SiN}_x\text{:Tb}^{3+}$ layers. The goal is to develop a layer that presents at the same time an efficient DS frequency conversion process, and anti-reflective property. Thus the composition and microstructure, as well as the optical properties of these systems will be studied.

2. Material and methods

The layers studied were deposited on p-type 250 μm -thick [001] 2" silicon (Si) substrates by radio-frequency reactive magnetron co-sputtering in a nitrogen-rich plasma. The matrix composition (Si/N ratio) was tuned by varying the Ar/ N_2 ratio (r_{N_2}) of the gas flux injected or the plasma pressure (P). In the case of the Tb^{3+} -doped system, the rare earth ions incorporation was controlled by the power density applied on the Tb target (RFP_{Tb}). This later was varied between 0.3 and 1.8 W/cm^2 . For all the undoped- and Tb^{3+} -doped SiN_x deposited layers, the target power density applied on the silicon target was fixed at 4.5 W/cm^2 in agreement with previous studies [28]. For all the samples, the deposition temperature was fixed at 200 $^\circ\text{C}$ while the deposition time was adjusted to obtain 90 nm-thick films whatever the deposition conditions. After deposition, the samples were annealed during 1 h by classical thermal annealing (CTA) at 850 $^\circ\text{C}$, under N_2 flow.

The composition of the studied layers has been investigated by means of Fourier Transform Infrared (FTIR) measurements. They were performed at room temperature using a Thermo Nicolet Nexus 750 II spectrometer working in the 4000–400 cm^{-1} range, with a resolution of 5 cm^{-1} . By fitting the obtained spectra with Gaussian functions, the vibration band positions were obtained.

Both the thickness and the complex refractive index of the studied layers were determined from ellipsometry measurements employing a UVISSEL Jobin-Yvon ellipsometer with an incident angle of 66.2°. The experimental I_e and I_s ellipsometry spectra were recorded on a 1.5–5 eV range with 0.01 eV resolution. The parameters (thickness and n) are determined by fitting the experimental data by a dispersion law derived from the Forouhi-Bloomer model [29] of amorphous semiconductors using the DeltaPsi2 software.

In order to study the emission and excitation properties, photoluminescence (PL) and photoluminescence excitation (PLE) experiments were performed at room temperature on the films. Specifically, the PL setup included a Lot-Oriel 1 kW-Xenon lamp connected to an OMNI300 monochromator used as a tunable light source. The PL spectra were

recorded with a Hamamatsu (R5108) photomultiplier tube after the dispersion of the PL signal by a MSH 300 OMNI monochromator. The detection system was locked in with a SR830 amplifier referenced at the excitation light beam chopped frequency. The PL and PLE spectra obtained were normalized by the sample thickness and the PLE spectra are also corrected by the excitation intensity.

The PL decays were measured using modified Quanta Master system from Photon Technology International (PTI). A pulsed 266 nm line of an actively Q-switched diode-pumped solid state YAG:Nd laser (Elforlight Ltd.) was used in this experiment as the excitation source. The PL decay traces were measured at the emission wavelength of 545 nm, corresponding to the main $^5\text{D}_4$ – $^7\text{F}_5$ transition of Tb^{3+} ions. The time resolution about 1 μs is small enough to resolve correctly the Tb^{3+} PL lifetimes.

A simulation program based on the transfer matrix method (TMM) [30] was run based on the deduced ellipsometric parameters (complex refractive index of a layer, substrate, superstrate and stack of layers, and thicknesses) to calculate the absorbance A , reflectance R , and transmittance T of the fabricated DS films deposited on top of a silicon SC. In addition, values representing the layer and its interaction with the AM1.5 solar spectrum [31] are defined. The absorbance efficiency (A_{eff}) is defined by the integration of the absorbance A convoluted by the solar irradiance spectrum ($I_{\text{AM1.5}}$) and normalized by the integrated solar irradiance spectrum ($I_{\text{AM1.5}}$):

$$A_{\text{eff}} = \frac{\int_{\lambda_{\min}}^{\lambda_{\max}} A(\lambda) I_{\text{AM1.5}}(\lambda) d\lambda}{\int_{\lambda_{\min}}^{\lambda_{\max}} I_{\text{AM1.5}}(\lambda) d\lambda} \quad (1)$$

The reflectance (R_{eff}), and transmittance (T_{eff}) efficiencies are defined similarly using the reflectance R , and the transmittance T respectively. A_{eff} , R_{eff} and T_{eff} represent the fraction of the sunlight that is absorbed, reflected and transmitted respectively by the layer over a given spectral range. Those values may be compared over different wavelength ranges and allow an easy comparison between samples.

The light emission and propagation in our samples were studied thanks to an 3×3 extended transfer matrix method (ETMM) coupled with electric dipole emitters [32–34]. This method uses the ellipsometric parameters (refractive indexes and thicknesses) of the sample and the surrounding media. With this method we can deduce the emission distribution as a function of the wavelength and the emission angle in each considered medium. The Tb^{3+} spectral line shape was assumed to be described by Gaussian functions representing the $^5\text{D}_4$ to $^7\text{F}_6$ and $^5\text{D}_4$ to $^7\text{F}_5$ energy transitions of the Tb^{3+} ions (Fig. 1). PL spectra were obtained by the integration over emission angles in the conversion layer, air, and silicon material substrate (wafer or SC). A supplementary integration over the bandwidth led to the luminescence integrated over the spectral range I_{PL}^i in each of the three media i

Fig. 1. Modeled Tb^{3+} PL spectra recorded in the three media, only the two more intense peaks/bands representing the $^5\text{D}_4$ to $^7\text{F}_6$ and $^5\text{D}_4$ to $^7\text{F}_5$ energy transitions are considered.

(layer, air, and silicon) and consequently to the global emission properties:

$$I_i^{PL} = \int_{Tot} I_i(\lambda) d\lambda \quad (2)$$

The integrated luminescence efficiencies η_i^{lum} in each medium is defined by the following equation:

$$\eta_i^{lum} = \frac{I_i^{PL}}{I_{air}^{PL} + I_{layer}^{PL} + I_{substrate}^{PL}} \quad (3)$$

3. Results and discussion

In this section, the composition and microstructure of the two systems (SiN_x and $\text{SiN}_x:\text{Tb}^{3+}$) will be first studied, followed by the analysis of their optical properties. Finally, an optimized Tb^{3+} -doped SiN_x layer will be presented and compared with our previous work on $\text{SiO}_x\text{N}_y:\text{Tb}^{3+}$ film. The internal quantum efficiency (IQE) of a Si-SC covered by this optimized DS layer will also be detailed.

3.1. SiN_x matrix

3.1.1. Microstructure

Fig. 2 exhibits transmittance FTIR spectra of a typical SiN_x layer conducted at both normal (in red) and Brewster (65°) (in black) angles. In both spectra, we can see the presence of two vibration bands peaking at 1121 cm^{-1} and 847 cm^{-1} . Ordinarily, only the TO band at 847 cm^{-1} may be seen under normal incidence analysis, but the amorphous character of the layers leads to a possible contribution of the LO peaks even under such incidence angle [35]. As expected, there is no signature of bands corresponding to either Si-O bond at around 1200 cm^{-1} , Si-H bond between 2200 and 2090 cm^{-1} , or N-H bond between 3320 and 2500 cm^{-1} .

The absence of Si-O related bands around 1200 cm^{-1} confirms that the two bands peaking at 1121 cm^{-1} and 847 cm^{-1} may only originate

Fig. 3. Refractive index of as grown SiN_x films as a function of the plasma pressure, P , for a nitrogen ratio, rN_2 , fixed at 20%. The red line corresponds to the stoichiometric material Si_3N_4 refractive index value. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

from the Si-N bond.

The inset of Fig. 2 displays the evolution of the position of the LO band of the Si-N bond (blue dots) as well as the refractive index at 1.95 eV (black squares) as a function of the nitrogen ratio rN_2 . When rN_2 increases, the $\text{LO}_{\text{Si-N}}$ band position shifts toward the high wave-numbers (blueshift) by 10 cm^{-1} which is a small relative variation, while the refractive index at 1.95 eV value decreases. Such evolution has already been observed by Debieu et al. [28] over a larger rN_2 domain ranging from 0% to 29% and therefore with a larger blueshift variation of 50 cm^{-1} . This smaller $\text{LO}_{\text{Si-N}}$ peak blueshift is consequently consistent with a smaller rN_2 range. According to the works of Huang

Fig. 2. FTIR spectra of as grown SiN_x films at normal and 65° (Brewster angle) incidences. The inset shows the LO band position and the refractive index as a function of the nitrogen ratio (rN_2) for a plasma pressure (P) fixed at 3 mTorr.

Fig. 4. FTIR spectra at Brewster angle for different annealing temperatures.

et al. [36] and Debieu et al. [28] on O- or H-free SiN_x films, such a blueshift of the $LO_{\text{Si-N}}$ vibration band can be ascribed to a decrease of the $[\text{Si}/\text{N}]$ ratio. Such matrix composition change leads to a shortening of the Si-N bond [37], or to an increase in the matrix disorder due to nitrogen excess. These phenomena are also compatible with the observed decrease of the refractive index at 1.95 eV (inset Fig. 2).

The effect of the plasma pressure P on the microstructural characteristic of the grown layer has been also investigated for rN_2 , fixed at 20%. Fig. 3 shows the decrease of the refractive index at 1.95 eV by 0.11 (4 times the measurement uncertainty) while P increases. Such

evolution can be ascribed to a decrease of the $[\text{Si}/\text{N}]$ ratio due an incorporation of nitrogen with higher plasma pressure as detailed above according to the work of W.R. Knolle as well as of Gardeniers et al. [38,39].

After deposition, the films are submitted to a CTA treatment during one hour in a nitrogen flux. The influence of the annealing temperature on the microstructure of the films has been studied and the corresponding FTIR spectra registered under Brewster incidence are presented in Fig. 4. Increasing annealing temperature favors the increase of $LO_{\text{Si-N}}$ band intensity with a concomitant shift of its position to higher wavenumbers. Considering that the film composition remains unchanged during this process, this evolution is attributed to the decrease of the disorder resulting from the reorganization of the matrix upon annealing. Such a decrease of the matrix disorder is confirmed by the lower overlapping of $TO_{\text{Si-N}}$ and $LO_{\text{Si-N}}$ bands around 1000 cm^{-1} [28].

3.1.2. Optical properties

The development of downshifting layer should meet important criteria prior to be used in a SC. Due to the low absorption cross section of the rare earth ions mentioned above, Tb^{3+} ions require the presence of efficient sensitizers able to absorb the solar energetic photons and transfer their energy to the rare earth ions for promoting at least the excitation of the electron from the 7F_6 to the 5D_4 energy level. As the downshifting layer will be placed on the top of the Si solar cell, it should require the following three criteria: (i) a low absorbance of photons having an energy lower than 2.54 eV (488 nm) to allow their conversion within the Si-SC but should also emit the downshifted

Fig. 5. A_{eff} as a function of n and d in the DS (a) and Non-DS (b) ranges, and T_{eff} as a function of n and d in the DS (c) and Non-DS (d) ranges.

photons with a high extraction into the SC, (ii) a low absorbance and a high transmittance of photons in the 1.1–2.54 eV energy range, and (iii) a low reflectance in order to collect as much as possible the light into the SiN_x layer-Si-SC system.

3.1.2.1. Refractive index properties. Before depositing our layers, we study the R_{eff} , A_{eff} , and T_{eff} described in the “Material and methods” part and that represent the calculated reflectance, absorbance, and transmittance efficiencies as a function of the static refractive index n and the thickness of the layer d for a constant extinction coefficient ($k=0.008$).

Two wavelength domains have to be defined before any analyses. One where the doped-SiN_x layer will play its role of frequency conversion, which corresponds to the 300–488 nm range noted DS, and one where it should be as transparent as possible. This later ranges from 488 to 1200 nm is noted Non-DS.

As previously mentioned, we seek a layer with a high absorbance and low transmittance in the DS range while having low absorbance and high transmittance in the Non-DS range. In addition, the reflectance has to be low on the whole spectral range.

Fig. 5 displays A_{eff} as a function of n and d in the DS (Fig. 5a) and Non-DS (Fig. 5b) ranges as well as T_{eff} as a function of n and d in the DS (Fig. 5c) and Non-DS (Fig. 5d) ranges. The absorbance and the transmittance should thus ideally be gate functions. However the monotonous behavior of the refractive index of the materials used does not allow such feature. A compromise has to be done between high absorbance in the DS range and high transmittance in the Non-DS one. Then the thickness should be smaller than 100 nm and the refractive index at 1.95 eV smaller than 2.2.

Fig. 6 shows R_{eff} as a function of n and d in the total range (DS and Non-DS ranges). The couple $n=2.0$ and $d=80$ nm shows the lower reflectance. However, in order to keep such high anti-reflective properties with a varying refractive index, the thickness has to be tuned consequently. In this range of n and d , an increasing n should be compensated by a decreasing d . Thus, the couple $n=2.2$ and $d=70$ nm also leads to high anti-reflective properties. By examining Fig. 6, we may determine that the layer thickness should not go over 100 nm with a preference for 80–70 nm and the refractive index at 1.95 eV should stay between 2.0 and 2.2 (white squares on Figs. 5 and 6).

After determining by modeling the optimal characteristics of the future DS layers, SiN_x host matrix is deposited varying P and rN_2 . Reflectance, absorbance, and transmittance curves of the deposited layers are deduced from the ellipsometric experimental measurements as a function of rN_2 . However, it is difficult to compare those curves for different layers. Thus, we will use the absorbance A_{eff} , reflectance R_{eff} ,

Fig. 6. R_{eff} as a function of n and d in the full range (DS and Non-DS ranges) (300–1200 nm).

and transmittance T_{eff} efficiencies described in the “Material and methods” part. As explained above, those values allow to describe the interaction between the light of the AM1.5 solar irradiance spectrum and the DS layers on different spectral ranges, and therefore to let an easier comparison. A_{eff} and T_{eff} are analyzed in the DS range (300–488 nm) and the Non-DS range (488–1200 nm). Fig. 7 exhibits A_{eff} and T_{eff} of the layers for different rN_2 for a P fixed at 3 mTorr (Fig. 7a and c) and different P for a rN_2 fixed at 20% (Fig. 7b and d). The red lines represent the Si₃N₄ reference. It is important to note that the values of A_{eff} and T_{eff} are similar in the two ranges due to the monotonous refractive index evolution over the full spectral range.

Regarding the effect of the nitrogen ratio rN_2 , A_{eff} increases and T_{eff} decreases with the increase of rN_2 . This behavior is more pronounced for the layers with a rN_2 higher than 20%. For those last two layers the absorbance is very high, and the transmittance very low, in the DS range but also in the non-DS one which is a major drawback for solar cell applications. For rN_2 of 14% and 17%, the absorbance is closer to the one of the Si₃N₄ reference which is interesting for the Non-DS part but useless in the DS one since it will not favor the sensitization of the rare earth ions.

The calculated reflectance efficiency (R_{eff}) in the full range (300–1200 nm) is reported in Fig. 8 as a function of rN_2 (Fig. 8a), and of P (Fig. 8b). Those values are compared to the R_{eff} of a Si₃N₄ reference layer (red line). This figure shows that the layers displaying the lower reflectance are those fabricated with $P=4$ mTorr (when $rN_2=20\%$) and $rN_2=25\%$ (when $P=3$ mTorr). However, considering our reference, the layers fabricated with $P=2$ and 3 mTorr and $rN_2=20\%$ have a R_{eff} close to the red line and still present high anti-reflective characteristics. The pressure P does not seem to influence significantly the R_{eff} while the rN_2 values have to be between 20% and 25% to produce layers meeting one of the above-mentioned criteria. The best trade-off for a sample with low R_{eff} and, high A_{eff} in the DS range and low A_{eff} in the Non-DS range is obtained for a nitrogen ratio rN_2 of 20% and a plasma pressure P of 3 mTorr.

Regarding the effect of the plasma pressure P , the best layer with high absorbance and low transmittance efficiencies in the DS part is the one deposited with a P of 4 mTorr. However, its absorbance efficiency is also very high, and its transmittance efficiency very low, in the non-DS part of the spectrum that will strongly decrease the efficiency of the Si solar cell. The analysis of the two other samples deposited with a P of 2 mTorr and 3 mTorr present lower absorbance and higher transmittance efficiencies in the non-DS range with a slightly higher absorbance and lower transmittance efficiencies for the 2 mTorr grown layer (by 4% and 0.72% respectively). However, they also present similar lower absorbance efficiencies in the DS one with respect to the 4 mTorr grown layer. Thus, P and rN_2 values under 3 mTorr and 20% respectively have to be chosen to produce layers meeting one of the above-mentioned criteria, even if in the non-DS part, such a SiN_x layers absorbs more photons than the Si₃N₄ one.

The increase of absorbance efficiency with rN_2 and P may be linked to the increase of nitrogen content in the matrix which allow a higher nitrogen defects concentration [40,41]. The resulting nitrogen defects states in the gap of the matrix will lead to larger photons absorption.

According to the absorbance and transmittance efficiencies, the criteria previously mentioned (low reflectance on the whole solar spectrum, high absorbance and low transmittance in the DS range, and low absorbance and high transmittance in the Non-DS range) are reached in the range of rN_2 between 14% and 20%, and P below 3 mTorr. However, the reflectance efficiencies show (Fig. 8) that it might be interesting to also look for rN_2 between 20% and 25% to improve the anti-reflective properties of the layers. The best compromise is thus the layer deposited with a nitrogen ratio rN_2 of 20% and a plasma pressure P of 3 mTorr.

3.1.2.2. Photoluminescence. Fig. 9 shows photoluminescence (PL) results of SiN_x layers measured as a function of the plasma pressure P

Fig. 7. Absorbance A_{eff} and transmittance T_{eff} efficiencies of SiN_x layers on the DS and Non-DS ranges as a function of rN_2 for P fixed at 3 mTorr (a) and (c) and as a function of P for a rN_2 fixed at 20% (b) and (d) respectively. The red line corresponds to the absorbance ((a) and (b)) and the transmittance ((c) and (d)) of a Si_3N_4 anti-reflective layer as a reference. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

and the nitrogen ratio rN_2 . The PL of the annealed SiN_x layers demonstrates the existence of distinct states in the matrix bandgap. Only the states that underwent radiative de-excitation are revealed. A multi-peaks fit (modeling peaks thanks to Gaussian curves) shows that the PL spectra are composed of three to four peaks depending on the deposition parameters. The position of those broad peaks due to the density of states of the defects is displayed in Fig. 9b.

A correspondence is found between the experimental (Fig. 9b) and theoretical energy transitions [442–47] that may thus be associated to specific electronic transitions, as reported on Fig. 10. However, it is important to note that the energy levels associated to the $\equiv\text{Si-Si}\equiv\sigma$

and σ^* as well as $=\text{N}^-$ centers are close to the conduction and valence bands (0.5 eV or less). In consequence the broad observed emission band arises from the transitions between those various energy levels:

- The peak (1), at 370 nm (3.3 eV) may correspond to the 3.1–3.6 eV transitions associated to the electronic transition occurring from (E_c or $\equiv\text{Si-Si}\equiv\sigma^*$) to ($=\text{N}_2^+$) and from ($=\text{N}_4^+$) to ($=\text{N}^-$, $\equiv\text{Si-Si}\equiv\sigma$, or E_v) (red arrows in Fig. 10). With E_c the energy level of the conduction band with the lowest energy and E_v the energy level of the valence band with the highest energy.
- The peak (2), at 440 nm (2.8 eV) may correspond to the 2.5–3.0 eV

Fig. 8. Reflectance efficiency R_{eff} at the air/layer interface of SiN_x layers as a function of rN_2 for P fixed at 3 mTorr (a) and as a function of P for rN_2 fixed at 20% (b). The red line corresponds to the reflectance of a Si_3N_4 anti-reflective layer as a reference. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

transitions associated to the electronic transition occurring from ($\equiv Si^\cdot$) to ($\equiv N^\cdot$, $\equiv Si-Si \equiv \sigma$, or E_v) (green arrow in Fig. 10).
 – The peak (3), at 490 nm (2.5 eV) may correspond to the 2.2–2.7 eV transitions associated to the electronic transition occurring from (E_c or $\equiv Si-Si \equiv \sigma^*$) to ($\equiv Si^\cdot$) and from ($\equiv Si^\cdot$) to ($\equiv N^\cdot$, $\equiv Si-Si \equiv \sigma$, or

E_v) (violet arrows in Fig. 10). It also might correspond to the 2.0–2.4 eV associated to the electronic transition occurring from (E_c or $\equiv Si-Si \equiv \sigma^*$) to ($\equiv Si^\cdot$) (violet arrows in Fig. 10).
 – The peak (4), at 585 nm (2.1 eV) may correspond to 1.3–1.8 eV transitions associated to the electronic transition occurring from (E_c

Fig. 9. (a). Photoluminescence spectra (black curves) of the SiN_x layers using a grating of 1200 lines/mm-300 blaze wavelength (bw) for a rN_2 and P fixed at 20% and at 3 mTorr, respectively. The experiments are carried out under a 285 nm excitation wavelength. The red curves are the fit made of several Gaussian curves (blue curves). (b) Position of the various peaks as a function of rN_2 . (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

Fig. 10. Energy level diagram of the SiN_x matrix with the energy level transitions observed in the literature [42–46] and the energy transfers possible and observed on Fig. 9.

or $\equiv\text{Si-Si} \equiv \sigma^*$ to $(=N_4^+)$, from $(=N_2^0)$ to $(=N^-)$, or/and from $(\equiv\text{Si-Si} \equiv \sigma, \text{ or } E_v)$ and $(=N_4^+)$ to $(=N_2^0)$ (orange arrows in Fig. 10).

For the layer deposited with rN_2 of 14%, the PL intensity reaches 3.9 arb.unit and decreases by a factor 2 for rN_2 equal to 17% or 20%. For highest value (25% and 30%), PL peaks are close to the background noise and therefore not distinguishable. The higher PL intensity is obtained for a P of 3 mTorr, whereas for the other values the PL signal is not distinguishable.

Note that the second peak (red dots on Fig. 9b), associated to the electronic transition occurring from $(\equiv\text{Si}^-)$ to $(=N^-)$, $\equiv\text{Si-Si} \equiv \sigma$, or E_v) (at 440 nm or 2.8 eV), appears only for the 14% and 17% nitrogen ratio. This may be due to the decreasing silicon content proportionally to the nitrogen one that will decrease the number of Si-Si bonds in favor of the Si-N ones. As a result, the silicon related defects $(\equiv\text{Si}^-)$ and $(\equiv\text{Si-Si} \equiv \sigma^* \text{ and } \sigma)$ number will decrease and lead to the disappearance of the electronic recombinations occurring from those levels (peak (2)).

Following the same reasoning the electronic transitions from $(E_c \text{ or } \equiv\text{Si-Si} \equiv \sigma^*)$ to $(\equiv\text{Si}^-)$ (violet arrow to the right) is less probable than the ones from $(E_c \text{ or } \equiv\text{Si-Si} \equiv \sigma^*)$ to $(\equiv\text{Si}^0)$ and from $(\equiv\text{Si}^0)$ to $(=N^-)$, $\equiv\text{Si-Si} \equiv \sigma$, or E_v). Indeed, the third peak is present for all the rN_2 values while the second peak that features the $\equiv\text{Si}^-$ energy level is present only for the lowest rN_2 values.

Thus, the defect states in the bandgap of SiN_x matrix are at the origin of the emissions at around 370 nm (3.34 eV), 440 nm (2.81 eV), and 490 nm (2.52 eV). These energies are in resonance with the energy levels of Tb^{3+} ions (5G_6 , 5D_3 - 7F_6 , 5D_3 - 7F_4 , 5D_4 - 7F_6). This makes defect states from SiN_x matrix potential sensitizers of Tb^{3+} ions via non-radiative transfer energy.

3.2. $\text{SiN}_x\text{:Tb}$ system

In the following, the optimized Tb^{3+} content in SiN_x host matrix will be investigated through the PL intensity of the Tb^{3+} ions peaks. As shown on Fig. 11a, four emission peaks can be observed corresponding to the transitions from the 5D_4 to the 7F_i levels as presented on Fig. 11b. Note that the emission spectrum has been achieved under a low photon

flux (1.9×10^{15} photons/cm²) excitation at 300 nm for the Tb^{3+} ions which has a low absorption cross section below 2×10^{-21} cm² as reported in [27,46]. Such a result evidences an efficient indirect excitation of Tb^{3+} ions which may witness a sensitization of the Tb^{3+} ions by defect states of the matrix. Such an excitation process has already been evidenced in Tb^{3+} -doped SiO_xN_y and $\text{Tb-Si}_x\text{O}_y$ systems [23,24].

The influence of the Tb incorporation on the emission properties of the $\text{SiN}_x\text{:Tb}^{3+}$ layer is presented in Fig. 12 in which the PL spectra recorded in the 330–720 nm range are reported for different RF power densities applied on the Tb target. The left part of the scale is related to the emission of the host matrix, ranging between 360 and 460 nm while the right part of the scale corresponds to the Tb^{3+} emission in the 460–720 nm range. All the layers have been annealed at 850 °C during one hour under a pure nitrogen flux. The PL of Tb-free SiN_x matrix is also reported on Fig. 12 showing a weak emission below 490 nm. In Tb-doped matrix, the PL associated to the defect states disappeared (Fig. 12) contrary to what was observed for non-doped matrix (Fig. 9a). This behavior suggests that an energy transfer may occur from the matrix defect states to the Tb^{3+} ions. In the 460–720 nm range, the increasing power density applied on the Tb target RFP_{Tb} favors the emission intensity of the Tb^{3+} ion which reaches its maximum for 0.45 W/cm² before decreasing and totally disappears for the highest RFP_{Tb} applied (1.8 W/cm²). Since the Tb^{3+} lifetime (Inset Fig. 12) shows a constant value of about 620 μs for RFP_{Tb} up to 0.45 W/cm², the observed increase of the Tb^{3+} emission intensity up to 0.45 W/cm² can be associated with the increase of optically active Tb^{3+} ions.

Above 0.45 W/cm², the decrease of intensity with RFP_{Tb} is attributed either to a concentration quenching process due to rare earth ions clustering [48,49] migrate or coupling Tb^{3+} ions with non radiative centers. This later point is confirmed by both the lifetime (inset of Fig. 12) and the FTIR measurements reported on Fig. 13. In the former, the terbium lifetime of the 5D_4 - 7F_5 transition remains constant (around 620 μs) up to $RFP_{\text{Tb}}=0.45$ W/cm². Indeed, below such RFP, the Tb^{3+} ions incorporation does not favor the creation of non-radiative de-excitation paths. After the RFP_{Tb} reaches values higher than 0.45 W/cm², the observed decrease of the Tb^{3+} lifetime (from 620 μs to 360 μs and 180 μs) is an evidence of the formation of two new kinds of non-radiative de-excitation channels. The first would be defects in the matrix that can trap the photons. The second would be an energy migration process between Tb^{3+} ions that become close enough to transfer energy among themselves and enhances the probability to reach a trap. In the FTIR measurements, the increase of RFP_{Tb} favors the overlapping of $TO_{\text{Si-N}}-LO_{\text{Si-N}}$ bands around 1000 cm⁻¹ as well as the decrease and the shift of the $LO_{\text{Si-N}}$ peak (Fig. 13). Such a feature is the signature of an increasing disorder and thus an increasing number of defects that may be responsible for the observed PL emission quenching and emission decay time decrease. Thus our optimum settings leading to the higher Tb^{3+} PL intensity are 0.45 W/cm² for the Tb target power density with a nitrogen rate of 20% rN_2 , and a plasma pressure of 3 mTorr.

Once the energy transfer from the host matrix to the Tb^{3+} ions has been proposed, its mechanism is detailed. A photoluminescence excitation (PLE) spectrum of the Tb-doped system was measured for a 545 nm detection wavelength ($^5D_4 \rightarrow ^7F_6$ transition) and displayed in Fig. 14. It can be seen that the doped system is mainly excited in the range of 240–290 nm (5.2–4.3 eV) and decreases then to the limit of detectability for excitation wavelengths longer than 335 nm (3.7 eV). This energy range may be associated with electronic transitions occurring from $(E_c \text{ or } \equiv\text{Si-Si} \equiv \sigma^*)$ to $(=N^-)$, $\equiv\text{Si-Si} \equiv \sigma$, or E_v). The broad energy distribution of electronic levels at the origin of energy transfer results in a broad PLE band. It is worth mentioning that the Full Width at Half Maximum (FWHM) of the PLE band is much broader than the FWHM of typical $f-d$ absorption bands of rare earth ions, which is another evidence for indirect excitation of these ions.

Fig. 11. (a) PL spectrum of a Tb-doped SiN_x under 300 nm excitation wavelength. (b) Energy level scheme of the Tb^{3+} ions.

Fig. 12. PL measurements of the host matrix in the 330–460 nm range (Left scale) and of the Tb emission in the 460–740 nm range (Right scale) of undoped and Tb-doped SiN_x layers. The PL measurements have been carried out using a grating of 1200 s/mm-300 blaze wavelength (bw) and an excitation wavelength of 266 nm. In inset, the Tb^{3+} lifetime for various RFP_{Tb} are exposed.

Fig. 14 also shows that the Tb^{3+} ions, due to their discrete energy structure, are excited mostly in their high energy levels such as the $4f_75d$ energy band and the $^5H_{6,7,8}$ and $^5F_{6,7,8}$ energy levels. This excitation occurs via energy transfer originating from the electronic transition from (E_c or $\equiv \text{Si-Si} \equiv \sigma^*$) to ($=N^{\cdot-}$, $\equiv \text{Si-Si} \equiv \sigma$, or E_v). The Tb^{3+} ions then undergo non-radiative de-excitation till reaching the 5D_4 energy level from which the four characteristic radiative transitions ($^5D_4 \rightarrow ^7F_x$ with $x=3, 4, 5$, and 6) take place.

3.3. Comparison of the $\text{SiN}_x\text{:Tb}^{3+}$ and $\text{SiO}_x\text{N}_y\text{:Tb}^{3+}$ systems

The optimized Tb^{3+} -doped SiN_x layer obtained is compared to an

optimized Tb^{3+} -doped layer made with a silicon oxynitride matrix, SiO_xN_y previously studied in our team [25]. The Tb^{3+} ions PL peaks at 285 nm excitation wavelength of our optimized sample is found to be 2.3 times more intense than the optimized sample obtained on the $\text{SiO}_x\text{N}_y\text{:Tb}^{3+}$ system (Fig. 15). However, considering an application to Si-SCs, the main parameter is not the light that is extracted toward the air but the light extracted toward the substrate, i.e. the SC. As such value is difficult to access experimentally, we calculated it based on ETMM method detailed in Material and methods part (§2) and on experimental PL data recorded in the air.

It has been shown [50] that the Tb^{3+} PL intensity in the air, $I_{\text{air}}^{\text{PL}}$, is given by:

Fig. 13. FTIR spectra at Brewster angle of the Tb-doped SiN_x layers for different Tb target RF power densities.

Fig. 14. PLE spectrum of the SiN_x:Tb³⁺ film for a detection wavelength of 545 nm and energy level diagram of the Tb³⁺ ion with the energy transfer from the matrix in blue and violet arrows, the non-radiative de-excitation in black straight dashed line arrows, and the radiative de-excitation in colored arrows. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

$$I_{air}^{PL} = C \frac{N^* \cdot V}{\tau_{rad}}, \quad (4)$$

with C an experimental constant, V being the volume on which the PL excitation is applied, N^* being the excited state population density, and τ_{rad} being the Tb³⁺ radiative lifetime. In our experiment, the volume of interaction (77.10^{-6} mm^3) and the pump power density Φ (1.9×10^{15} photons/cm²) are constant. Assuming a constant τ_{rad} (around 620 μs in both matrices) and a low pump power density approximation, we can express the excited state population density as:

$$N^* = K\sigma\Phi\tau_{rad}N_{tot} \quad (5)$$

With K an experimental constant, N_{tot} the total population density of Tb³⁺ ions, and σ the effective excitation cross-section.

Thus the ratio of the PL intensities in the air can be written as (from Eqs. (4) and (5)):

Fig. 15. Photoluminescence spectra of the optimized samples obtained of Tb³⁺-doped SiO_xN_y and SiN_x doped terbium matrices for a 285 nm excitation wavelength measured with the 600 lines/mm-750 bw grating.

$$\frac{I_{air}^{PL}(\text{SiN}_x)}{I_{air}^{PL}(\text{SiO}_x\text{N}_y)} = \frac{N_{tot}(\text{SiN}_x)}{N_{tot}(\text{SiO}_x\text{N}_y)} \cdot \frac{\sigma_{air}(\text{SiN}_x)}{\sigma_{air}(\text{SiO}_x\text{N}_y)} = 2.3 \quad (6)$$

RBS measurements on both layers are reported in the table as shown elsewhere [26,47].

Thus, the ratio of total population densities is:

$$\frac{N_{tot}(\text{SiN}_x)}{N_{tot}(\text{SiO}_x\text{N}_y)} = 1.8 \quad (7)$$

The effective excitation cross-section in the air that represents the mechanisms of absorption and energy transfer between the matrix and the Tb³⁺ ions in the layer as well as the extraction of the Tb³⁺ emission (at 501 nm and 557 nm) from this layer to the air. The ratio of such effective excitation cross-section of the SiN_x matrix over the SiO_xN_y one can thus be given by:

$$\frac{\sigma_{air}(\text{SiN}_x)}{\sigma_{air}(\text{SiO}_x\text{N}_y)} = \frac{I_{air}^{PL}(\text{SiN}_x) \cdot N_{tot}(\text{SiO}_x\text{N}_y)}{I_{air}^{PL}(\text{SiO}_x\text{N}_y) \cdot N_{tot}(\text{SiN}_x)} = 1.3 \quad (8)$$

The ETMM program yields the integrated luminescence efficiencies η_i^{lum} in the layer, in the air, and in the substrate. They are given in Table 2. We can see that the SiN_x layer transfers more to the SC (modeled here by the Si) than the SiO_xN_y layer.

The ratio of the effective excitation cross-section in the air (Eq. (8)) represents the DS efficiency with extraction in the air. However for silicon solar cell applications, we may be interested in the DS efficiency with extraction in the silicon SC. In order to evaluate this DS efficiency with extraction in silicon, we use the Eqs. (3) and (8) and the integrated luminescence efficiencies of Table 2 to obtain the ratio of the effective excitation cross-section in the layer and in the substrate (Si-SC):

$$\frac{\sigma_i(\text{SiN}_x)}{\sigma_i(\text{SiO}_x\text{N}_y)} = \frac{\eta_i^{lum} / \eta_{air}^{lum} \cdot \sigma_{air}(\text{SiN}_x)}{\eta_i^{lum} / \eta_{air}^{lum} \cdot \sigma_{air}(\text{SiO}_x\text{N}_y)} \quad (9)$$

This equation leads to a ratio of effective excitation cross-section of the SiN_x matrix over the SiO_xN_y one of 1.9 calculated in the layer and of

Table 1
Composition of the Tb-doped SiN_x and SiO_xN_y matrices [24,47].

Samples	Si at%	N at%	Tb at%	O at%
SiN _x : Tb ³⁺	42	56	1.5	-
SiNxOy:Tb ³⁺	33	46	1	20

Table 2

Integrated luminescence efficiencies of the SiN_x and SiO_xN_y matrixes in the air, the layer, and the silicon.

η^{lum} (%)	Air	Layer	Silicon
SiN_x	8.7	56.3	35
SiN_xO_y	13.8	60.2	26

Fig. 16. Scheme of the process fabrication of the solar devices with the developed nitride layers.

2.7 calculated in the substrate (Si-SC).

This ratio shows the improvement of the DS efficiency of the SiN_x layer compared to the thicker SiN_xO_y one in the silicon. Part of this difference may be attributed to different thicknesses (225 nm and 93 nm) and different refractive indexes (1.65 and 2.02) for the $\text{SiO}_x\text{N}_y\text{:Tb}^{3+}$ and $\text{SiN}_x\text{:Tb}^{3+}$ respectively. For the conditions of thickness and refractive index employed in this work, the silicon, and thus the silicon solar cells, would receive 5 times more light at 501 nm and 557 nm from the Tb^{3+} -doped SiN_x layer compared to the SiN_xO_y one. Thus the increase in the PL intensity is due to two contributions: on one hand to the increase in the Tb^{3+} ions incorporation in the SiN_x matrix

without formation of clusters, and on the other hand to the improvement of the conversion efficiency of the layer.

3.4. Device test

The Si-based nitride layers described above have been deposited on top of industrial crystalline Si solar cells. For this purpose, its deposition step has been integrated in the industrial cells fabrication process. Fig. 16 describes schematically the steps followed that corresponds to the standard procedure of the Si-PV industry [51] with the integration of the deposition of our layer. A 200 μm -thick monocrystalline p-type Si wafer is chemically cleaned and textured using a KOH etching prior to operate a n-type doping via a POCl_3 diffusion at 850 $^\circ\text{C}$ during 30 min. Afterwards, an isolation etching process is performed for removing the n-type Si at the edges and backsides. Thereafter a classical removed native oxide procedure is applied using a HF acid. Subsequently a 80 nm-thick Si-based nitride layer is then deposited by means of RF magnetron sputtering using the optimized fabrication conditions described above, before a post annealing treatment at 850 $^\circ\text{C}$ during 5 min to favor the recovering of non-radiative traps. The annealing time has been intentionally fixed at 5 min to avoid any damaging of the p-n junction through diffusion of the dopant. Then the last step of the process consists in screen-printing of Ag-front contacts and Al-back contacts followed by a co-firing.

A Tb^{3+} -doped and undoped SiN_x layers have been deposited to allow the observation of the rare earth doping effect on the optical properties of the device. Indeed, the standard anti-reflective layers of industrial solar cells are silicon nitride ones very close to our undoped layer. This undoped layer is thus used as a reference to determine the difference of efficiency brought by the deposition of the DS layer on top of the cells.

Reflectance measurements have been carried out on the system before depositing the metallic contact (Fig. 17a). This optical characteristic plays an important role in a future solar device since our objective consists in optimizing the ARC layer (Anti-Reflective Coating). The Reflectance values for both nitride layers are below the value of 5% in wide domain of wavelength ranging from 350 to 750 nm and a bump is observed after 1020 nm. The reflection efficiency in the 300–1200 nm range is of 6.04% for the device coated with the SiN_x ARC layer and reaches 6.20% by adding the rare earth ion. Such value demonstrates the high anti-reflective properties of the couple ARC layer whatever the nitride layer deposited.

The study of the IQE spectra (Fig. 17b) reveals that the Tb^{3+} -doped layer has a higher IQE than the undoped one from 300 to 900 nm with a

Fig. 17. (a) Reflectance characteristics of the SiN_x (black) and $\text{SiN}_x\text{:Tb}^{3+}$ (red) anti-reflective layers deposited on a textured Si surface. (b) IQE curves of a solar device with either the optimized SiN_x (black) or the optimized $\text{SiN}_x\text{:Tb}^{3+}$ (red) layers on top. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article).

particular increase of 15% in the UV range (300–400 nm). Above 900 nm one can note a slight decrease of the doped-layer with respect to the undoped one. This result shows that the IQE is larger for UV photons thanks to the Tb³⁺-doped layer. In addition, Fig. 17b displaying the reflectance of SC topped with our layers (undoped- and Tb³⁺-doped-layers) shows that the Tb³⁺-doped layer has a lower reflectance in the UV range which favors the absorption/or transmission of those photons by the layer/or to the cell. Regarding the IQE spectrum, the Tb³⁺-doped layer acts as a down-shifting layer that may improve the solar cell efficiency in the UV part of the solar spectrum. This result shows that such DS layer can be a promising solution for improving the Si-SC and that the process developed is fully compatible with the industrial process.

4. Conclusion

In this paper, both layers of SiN_x and layers of SiN_x:Tb³⁺ deposited by reactive magnetron co-sputtering had been studied in order to obtain a thin down-shifting layer that emits a maximum at 629 nm, 594 nm, 550 nm, and 493 nm (terbium peaks) and is also an anti-reflective layer. Studies of the composition, the microstructure, and the optical properties enabled a better understanding of the requirements for obtaining such a layer. Comparing those studies with photoluminescence analyses leads to a better understanding of the properties needed to reach a high terbium emission. An optimized layer has been determined for a plasma pressure of 3 mTorr, a nitrogen ratio n_{N_2} of 20%, and a 0.45 W/cm² power density on the terbium target. Such SiN_x-based optimized layer was found to transmit 5 times more down shifted light toward the solar cell than a comparable SiO_xN_y-based layer previously developed. For the monolithic crystalline Si solar cells with down-shifting layer, the IQE of the two optimized layers doped or not were compared. It was found that the down-shifting layer improves by 15% the IQE in the UV part of the solar spectrum. The next step will consist in determining the optical-electrical characteristic of the solar cell with a downshifting layer on the top.
