16 **Abstract**

17 In many liposome applications, the nanomechanical properties of the membrane envelope are
18 essential to ensure e.g. physical stability, protection or penetration into tissues. Of all factors,
19 the lipid composition and its phase behavior are susceptible to tune the mechanical properties
20 of membranes. To investigate this, small unilamellar vesicles (SUV; diameter <200 nm),

referred to as liposomes, were produced using either the unsaturated 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC) or the saturated 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) in aqueous buffer at pH 6.7. The respective melting temperatures of these phospholipids were -20°C and 41°C. X-ray diffraction analysis confirmed that at 20°C DOPC was in the fluid phase and DPPC was in the gel phase. After adsorption of the liposomes onto flat silicon substrates, atomic force microscopy (AFM) was used to image and probe the mechanical properties of the liposome membrane. The resulting force-distance curves were treated using an analytical model based on the shell theory to yield the Young's modulus (E) and the bending rigidity (k_C) of the curved membranes. The mechanical investigation showed that DPPC membranes were much stiffer ($E = 116 \pm 45$ MPa) than those of DOPC ($E = 13 \pm 9$ MPa) at 20°C. The study demonstrates that the employed methodology allows discrimination of the respective properties of gel- or fluid-phase membranes when in the shape of liposomes. It opens perspectives to map the mechanical properties of liposomes containing both fluid and gel phases or of biological systems.

I. INTRODUCTION

In the recent years, small unilamellar vesicles of phospholipids ($< \mu\text{m}$ diameter) have gained increasing interest in various liposome technologies, e.g. as drug delivery systems in pharmacy or as protective cargo capsules for cosmetics, nutraceuticals or for food design^{1,2}. They are also interesting models to investigate and possibly control *in vivo* biological signaling mechanisms involving extracellular vesicles such as the so-called exosomes^{3,4}. The

composition of the phospholipids, i.e. the acyl chains' saturation/unsaturation and length, impacts their phase state in the liposomes at ambient temperatures⁵. This, in turn, is likely to affect the mechanical properties of the liposomes, which are of paramount importance for these applications. Mechanical properties direct the stability, size, shape and fusion of the liposomes⁶⁻⁸ as well as the membrane fluidity/rigidity or permeability and hence their loading capacity or their ability to penetrate tissues⁹⁻¹³. For example, the permeability of various saturated polar lipid membranes to glucose strongly increases as the lipid undergoes gel-to-liquid disordered (l_d) phase transition¹⁴. As another example, milk sphingomyelin exhibited maximum permeability at temperatures where gel-to- l_d phase transition occurs¹³. This has important consequences on the formulation and design of liposomes, as the desirable mechanical properties will differ depending on the application and temperature, e.g. storage at ambient temperature, transdermal delivery of drugs, etc. Experimental techniques to measure the mechanical properties of liposomes, such as the pipette aspiration technique, osmotic or mechanical compression, shear-induced or optical tweezers deformation⁷ are often designed for large objects of the μm length scale. For liposomes at the nanoscale, such as small unilamellar vesicles, indentation measurement using atomic force microscopy (AFM) has proven a valuable and sensitive approach¹⁵⁻²⁰. The liposomes, adsorbed onto a flat substrate, are indented by the AFM with low penetration distances (i.e. the order of magnitude of the membrane thickness) and at as low force values as down to the pN. The major advantage of AFM over a nano-indenter is also its imaging capacity, which allows to locate liposomes and

to indent them centrally, even though not perfectly normally¹⁶. In a pioneering study, Laney et al.¹⁷ extracted synaptic liposomes (~110 nm diameter) from the electric organ of the electric ray *Torpedo californica*, immobilized them by adsorption onto mica and measured elastic moduli values in the range 0.2 – 1.3 MPa. Liang et al.^{19,21,22} followed the same approach on small (40-160 nm) liposomes of egg phosphatidylcholine (mainly stearylloleoylphosphatidylcholine, SOPC) and found that the elastic modulus increased with the addition of up to 50 mol % cholesterol from ~2 to 13 MPa. However, these authors used an adaptation of the Hertz model for their calculations that assumed the liposomes to be homogeneous filled spheres. By implementing the shell deformation theory, Delorme and Fery¹⁶ obtained higher elasticity values of ~110 MPa by indenting DPPC (dipalmitoylphosphatidylcholine) and proposed that the Hertz model underestimated the mechanical properties of the liposomes. However, due to its mono-unsaturation, egg PC has a melting temperature (T_m) of -15°C and is therefore in the l_d or liquid crystalline ($L\alpha$) phase at 20°C, while the fully saturated DPPC is in the gel or solid-ordered (s_o) phase (T_m = 41.7°C)^{22,23}. Therefore, it is yet to assess whether the AFM indentation measurement combined with the shell theory interpretation is sensitive enough to discriminate liposomes with presumably different mechanical properties of their membranes, e.g. by comparing saturated and unsaturated phospholipids in different physical phases at 20°C.

When the membranes are spread as two-dimensional supported lipid bilayers (SLBs), measurement of the rupture force of membranes using AFM indentation has proven to fully

81 resolve mechanical differences between phospholipids with various chain lengths, saturation
82 degrees or head groups²⁴. However, calculation of the SLBs' effective elasticity using
83 indentation of the membrane and the Hertz model requires careful and narrow experimental
84 conditions not to be affected by the support²⁵ Furthermore, direct measurement on small
85 liposomes would encompass possible curvature effects. Indeed, their high membrane
86 curvature may affect their mechanical properties, as lateral intermolecular distances and
87 forces vary across the bilayer's thickness^{26,27}. However, indentation measurements on 3D
88 vesicles may be either impossible²⁸, require high deformation of the objects¹⁹ or somewhat
89 depend on the composition of the internal medium, if different from the surrounding
90 medium²⁹. For these reasons, there is interest to assess indentation measurement of the
91 mechanical properties of membranes directly on volumetric objects such as liposomes.
92 In the present study, the respective elasticities and bending rigidities of membranes of either
93 the unsaturated phospholipid dioleoylphosphatidylcholine (DOPC) or the saturated
94 phospholipid dipalmitoylphosphatidylcholine (DPPC) as shaped in the form of liposomes,
95 were measured at 20°C using AFM indentation and the shell theory. The results were
96 discussed in light of the respective phase states of the two phospholipids at 20°C and showed
97 that AFM indentation is a sensitive method to assess the mechanical properties of 3D
98 membrane objects at the nanoscale.

99

100 **II. EXPERIMENTAL METHODS**

2.1. Materials

Pure phospholipids 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC; 18:1; >99%) and 1,2-dipalmitoyl-sn-glycero-3-phospholcholine (DPPC; 16:0; >99%) were purchased from Avanti Polar Lipids (Alabaster, AL). PIPES (1,4-piperazinediethanesulfonic acid) buffer was prepared as: PIPES 10 mM (purity $\geq 99\%$; Sigma-Aldrich, Milwaukee, WI, USA), NaCl 50 mM (Sigma), and CaCl_2 10 mM (Sigma) were dissolved in Milli-Q water and adjusted to pH 6.7 using NaOH 5 M.

2.2. Preparation of liposomes

Samples were prepared by dissolving appropriate quantity of the lipid powder of DOPC or DPPC in glass vials with chloroform/methanol (4:1 v/v). The organic solvent was then evaporated at 40 °C under a stream of dry nitrogen. The dried lipid films were hydrated with PIPES-NaCl- CaCl_2 buffer at 70°C to reach a final concentration of 0.1 wt. % lipids then thoroughly vortexed. Small unilamellar vesicles (SUV) were produced at 65°C by sonication using a Q700 equipment (Q-sonica, Newtown, CT, USA) and a microtip operating at 50% amplitude (~400 W) for 30 min. After sonication, the SUV suspension was left to cool and equilibrate at room temperature (20°C). The SUV produced according to this protocol will be designated as “liposomes” throughout this report.

2.3. Dynamic light scattering (DLS)

The size distribution and the average hydrodynamic diameter (D_h) of the vesicles were measured in PIPES-NaCl- CaCl_2 buffer at 20°C by dynamic light scattering (DLS) on a

1
2
3 121 Zetasizer Nano ZS (Malvern Instruments, Worcestershire, United Kingdom). Measurements
4
5
6 122 were carried out at a scattering angle of 173° and a wavelength of 633 nm. The average D_h ($\pm$
7
8
9 123 5 nm) was calculated from the intensity distribution using conversion into an autocorrelation
10
11 124 function which is then analyzed with the Stokes-Einstein relation, assuming that particles had
12
13
14 125 a spherical shape. The viscosity of the solution was 1.003 mPa.s at 20°C and the refractive
15
16
17 126 index of the solvent was 1.33.

127 **2.4. Differential scanning calorimetry (DSC)**

128 The thermotropic properties of DOPC or DPPC were measured on multilamellar vesicles
129 using a differential scanning calorimetry (DSC) Q1000 apparatus (TA Instruments,
130 Newcastle, USA). Multilamellar vesicles (MLV) were produced by rehydration of the lipid
131 films with PIPES-NaCl- CaCl_2 buffer at 65°C to reach a final concentration of 20 wt. % lipids,
132 then thorough vortex mixing. MLV are preferred over unilamellar vesicles in order to
133 accommodate the high bilayer concentration. They also allow higher resolution of the DSC
134 thermograms thanks to higher cooperativity of the molecules³⁰. The samples were introduced
135 in 20 μL aluminum pans that were then hermetically sealed. An empty pan was used as a
136 reference. The samples were heated at $2^\circ\text{C}.\text{min}^{-1}$ from -40°C to 70°C . The calibration of the
137 calorimeter was performed with indium standard (melting point = 156.66°C , ΔH melting =
138 28.41 J.g^{-1}). The thermal measurements were performed in triplicate. Standard parameters
139 were calculated by the TA software (Universal Analysis 2000, v 4.1 D).

140 **2.5. Temperature-controlled X-ray diffraction (XRD)**

1
2
3 141 X-ray scattering experiments were performed on the home-made Guinier beamline at IPR³¹.
4
5
6 142 A two-dimensional Pilatus detector with sample to detector distance of 232 mm allowed the
7
8
9 143 recording of XRD patterns in the range $0.013 \text{ \AA}^{-1}$ to $1.742 \text{ \AA}^{-1}$, thus covering both the small
10
11
12 144 and wide-angles regions of interest to characterize the lamellar structures and to identify the
13
14 145 packing of the acyl chains, respectively. Diffraction patterns displayed series of concentric
15
16
17 146 rings as a function of the radial scattering vector $q = 4 \pi \sin\theta / \lambda$, where 2θ is the scattering
18
19
20 147 angle and $\lambda = 1.541 \text{ \AA}$ is the wavelength of the incident beam. The channel to scattering vector
21
22
23 148 q calibration of the detector was carried out with silver behenate³². Small volumes (around 10
24
25 149 μL) of samples containing DOPC or DPPC vesicles were loaded in thin quartz capillaries of
26
27
28 150 1.5 mm diameter (GLAS W. Muller, Berlin, Germany) and inserted in the set-up at a
29
30
31 151 controlled temperature.

32 33 152 **2.6. Transmission electron microscopy (TEM)**

34
35
36 153 The observation of DOPC and DPPC Liposomes by cryo-TEM was realized as described in
37
38
39 154 previous work³³. The samples were prepared using a cryopluje cryo-fixation device (Gatan,
40
41
42 155 Pleasanton, CA, USA) in which a drop of the aqueous suspension was deposited on to glow-
43
44
45 156 discharged holey-type carbon-coated grids (Ted Pella Inc., Redding, CA, USA). The TEM
46
47
48 157 grid was then prepared by blotting the drop containing the specimen to a thin liquid layer
49
50
51 158 remained across the holes in the support carbon film. The liquid film was vitrified by rapidly
52
53
54 159 plunging the grid into liquid ethane cooled by liquid nitrogen. The vitrified suspension of
55
56
57 160 liposomes was mounted in a Gatan 910 specimen holder that was inserted in the microscope

161 using a CT-3500-cryotransfer system (Gatan, USA) and cooled with liquid nitrogen. TEM
162 images were then obtained from liposomes suspension preserved in vitreous ice and
163 suspended across a hole in the supporting carbon substrate. The samples were observed under
164 low dose conditions ($< 10 \text{ e}^-/\text{Å}^2$), at -178 °C , using a JEM 1230 'Cryo' microscope (Jeol,
165 Japan) operated at 80 keV and equipped with a LaB6 filament. All the micrographs were
166 recorded on a Gatan $1,35 \text{ K} \times 1,04 \text{ K} \times 12 \text{ bit}$ ES500W CCD camera.

167 **2.7. Atomic force microscopy (AFM)**

168 **2.7.1. Indentation of liposomes**

169 Simple open liquid sample cells were fabricated by gluing small ($\sim 0.5 \times 1 \text{ cm}^2$) pieces of
170 silicon substrate (molecular orientation 100) onto diagnostic glass slides (Thermo Scientific,
171 Waltham, MA, USA). After thorough cleaning of the cell with ethanol, water and UV/O_3 , the
172 liposome suspension equilibrated at 20°C was deposited onto the clean silicon surface then
173 left to incubate at 20°C for 30 min. The droplet was then gently exchanged with PIPES- NaCl -
174 CaCl_2 buffer at 20°C to remove the un-adsorbed liposomes. The sample was then imaged in
175 contact mode using an MFP-3D Bio AFM (Asylum Research, Santa Barbara, CA, USA), with
176 a typical scan rate of 1 Hz for $20 \times 20 \text{ }\mu\text{m}^2$ and 256×256 pixels images, silicon MLCT
177 probes (nominal spring constant $k \sim 0.03 \text{ N.m}^{-1}$ – Bruker Nano Surfaces, Santa Barbara, CA,
178 USA) calibrated extemporaneously using the thermal noise method, and loading forces
179 typically below 1 nN. Upon adsorption onto the flat surface, the spherical liposomes deform
180 into spherical cap geometry. AFM imaging of large area (typical size) allows localization of

the adsorbed liposomes, then closer images (typically $2 \times 2 \mu\text{m}^2$ or less) were recorded and sections were drawn across the images in order to measure the individual liposome's height (H) and base width (W). The AFM probe was then positioned above the center of each liposome and individual force curves ($n > 60$) were recorded with a set point of 200 pN, a distance of 100 nm and a Z-piezo speed of $2 \mu\text{m.s}^{-1}$. In these conditions, indentation of the AFM tip into the liposome did not exceed ~ 5 nm, thereby allowing measurement of the mechanical properties in the elastic regime of the membrane. The approach curves were then treated using the shell theory as described in the result section.

For data visualization and analysis, Gwyddion 2.47 software was also used, as a means to deduce the local radius of curvature (R_c) at the top of individual adsorbed liposomes over a distance of ~ 130 nm both sides of the apex (130 nm being the estimated radius of the membrane area affected by indentation by a 20-nm radius MLCT probe). The R_c values of individual liposomes were input in the calculation of the Young modulus (see below).

Measurement of the local R_c values at the apex of individual liposomes, instead of for the complete objects, avoided errors due to imperfect (e.g. flattened) spherical cap geometry of the liposome upon adsorption, and/or errors due to convolution by the AFM tip. The latter may indeed overestimate lateral dimensions of the liposomes by as much as the tip diameter, but can be avoided as long as near-normal contact is maintained between the tip and the liposomes, which is the case when measuring R_c at their apex.

2.7.2. Measurement of the bilayer thickness

201 Immediately after sonication at 65°C, 10 µg of the hot lipid suspension were deposited onto
202 freshly cleaved mica in an Asylum Research open liquid cell, then incubated at 65°C for 60
203 min. Slow cooling of the samples was performed using a programmed incubator as in Murthy
204 et al.³⁴ to yield supported lipid bilayers (SLB). Once equilibrated at 20°C, the bilayers were
205 extensively rinsed and exchanged with PIPES-NaCl-CaCl₂ buffer. AFM imaging of the
206 bilayers was then performed in the same buffer and in contact mode using MSNL probe
207 (nominal spring constant $k \sim 0.03 \text{ N.m}^{-1}$ – Bruker Nano Surfaces, Santa Barbara, CA, USA)
208 with the same imaging parameters already cited. The probes were calibrated
209 extemporaneously using the thermal noise method. Force spectroscopy curves were then
210 acquired at 20°C by using force-volume imaging of the bilayers (typically $10 \times 10 \text{ }\mu\text{m}^2$ or
211 less) with a typical set point of 20 nN and a piezo speed of $2\mu\text{m.s}^{-1}$.

212 **2.8. Statistical analysis**

213 The results are presented as mean value $\pm$ standard deviation. Analysis of variance was
214 performed using the General Linear Model procedure of Statgraphics Plus version 5
215 (Statistical Graphics Corp., Englewood Cliffs, NJ). Differences were significant for $p < 0.05$.

217 **III. RESULTS AND DISCUSSION**

218 **3.1. Phase state of DOPC and DPPC at 20°C**

219 The thermal phase behavior of unsaturated (18:1) DOPC and saturated (16:0) DPPC
220 phospholipids (chemical structures shown in Fig1.A) was examined using DSC and the

results were correlated with the structural analysis performed by XRD. Fig1.B shows the respective DSC heating thermograms of both lipids in the same conditions. For DOPC, the thermogram shows a very low temperature of L_{β} to L_{α} (gel to fluid) phase transition at $T_m = -20^{\circ}\text{C}$, in good agreement with previous reports^{11,35,36}. Meanwhile, the heating of DPPC revealed two endotherms, characteristic of the L_{β} (gel) to $P_{\beta'}$ (ripple) transition at $T_m = 37.09^{\circ}\text{C}$ and of the $P_{\beta'}$ (ripple) to L_{α} (fluid) transition at $T_m = 41.01^{\circ}\text{C}$, also in good agreement with previous reports^{34,35,37}. XRD experiments allowed identification of the lipid phases at 20°C (Fig. 1C). For this, the MLV are interesting not only to investigate the lateral packing of the acyl chains (at large q), but also to confirm the lamellar organization of the phospholipid (at small q). For DOPC, the absence of diffraction peak at wide angles and a lamellar organization characterized at small angles, confirmed the L_{α} phase of DOPC at 20°C . DPPC multilamellar vesicles exhibited a single broad peak at $q \sim 1.5 \text{ \AA}^{-1}$ corresponding to the formation of ordered phase packed in pseudo-hexagonal lattice and a lamellar organization at small angles, showing the formation of a $L_{\beta'}$ organization of DPPC at 20°C . The tilt of the acyl chains may have been induced by the multilamellar organization of the DPPC molecules in the vesicles. Since AFM experiments on DPPC molecules were performed in SUV, the ordered phase state of DPPC molecules in SUV at 20°C was also proved by XRD experiments performed on SUV of DPPC. As previously reported in literature³⁸, the high curvature of expected SUV of DPPC do not allow the recording of a peak at wide angles. Nevertheless, the Small Angles X-ray Scattering could be performed upon heating of the

SUV. Both high and low temperature spectra can be fitted as an individual membrane using equation (1):

$$I(q) = \frac{1}{q^2} \left[\frac{\sin(q.e_{HG}/2)}{q.e_{HG}} . e^{-(q.r)^2} + \frac{\sin(q.e_{CH2}/2)}{q.e_{CH2}} \right]^2 \quad (1)$$

with e_{HG} , the headgroup thickness, e_{CH2} , the aliphatic chain thickness and r the rugosity of the headgroup/water interface.

The full analysis demonstrates a contraction of 2Å of both e_{HG} and e_{CH2} at the gel-fluid transition at 40-44°C (Fig. 1D). This showed that the DPPC molecules in SUV are sensitive to temperature and consequently in the gel phase at room temperature. In conclusion, DSC and XRD confirmed that DOPC (unsaturated; $T_m = -20^\circ\text{C}$) and DPPC (saturated; $T_m = 41^\circ\text{C}$) were respectively present in fluid and gel phases at 20°C.

3.2. Morphology of the liposomes at 20°C

Electron microscopy, dynamic light scattering (DLS) and AFM imaging were used to characterize the morphology (size and shape) of the liposomes obtained after sonication (Fig 2). Cryo-TEM images showed that DOPC and DPPC vesicles were essentially unilamellar and spherically shaped. However, while DOPC liposomes consistently exhibited circular cross-sections (Fig 2A), DPPC could show both rounded and/or somewhat faceted membranes (Fig 2D). The presence of angle facets was attributed to the physical gel state of DPPC at 20°C³⁹. Cryo-TEM images revealed variable liposome diameters (from tens to

hundreds of nm) which corresponded to the size distribution measured by DLS (Fig 2B, E). For DOPC, the size distribution was monomodal with a mean diameter D_h at 120 ± 69 nm (Fig 2.B). Whereas, DPPC liposomes exhibited a shouldered size distribution with a mean diameter D_h of 132 ± 73 nm for the whole distribution (Fig 2.E; Table1). In the next step, the liposomes were immobilized by adsorption onto silicon to be first imaged then indented using an AFM probe. Images recorded in contact mode showed that DOPC and DPPC liposomes were perfectly stable on the flat substrate. However, it was not possible to prevent non-destructive deformation due to adsorption, as previously reported^{19,40}. The AFM images were also used to measure the height H and basal width W of adsorbed individual liposomes in order to prove that objects observed in AFM images corresponded truly to liposomes. To do this, the adsorbed liposomes were considered to adopt a spherical cap geometry and their volume was calculated as:

$$V = \frac{\pi H}{6} \left(\frac{3}{4} W^2 + H^2 \right) \quad (2)$$

From (Eq.2), the mean diameter of a sphere of equivalent volume was inferred and compared with DLS data (Table 1; Figures 2B and E). The mean diameter values were of similar orders of magnitude in both methods; and whatever the method used, DOPC liposomes always exhibited smaller diameters than DPPC ones. This confirmed that the adsorbed objects visible on the AFM images truly were liposomes. However, the mean diameter results measured by AFM were higher than DLS probably because larger liposomes were preferably chosen out of

large-area images (such as shown on Figure 2) to perform close-up views and indentation measurements (Table1).

3.3. Mechanical properties of liposomes as a function of phase state at 20°C

3.3.1. Bilayer thickness

The average bilayer thickness d was measured in the conditions used in this work: temperature 20°C, pH=6.7, 50 mM NaCl and 10 mM CaCl₂. This measurement was performed using atomic force spectroscopy on SLB of DOPC or DPPC spread onto freshly cleaved mica. Average values of d were obtained from measurements performed on various regions of different samples (n=50). In a typical force spectroscopy experiment, the AFM tip approaches the surface until a mechanical contact with the SLB is established. Then, the bilayer is elastically deformed by the AFM probe until the tip ruptures (breaks through) the membrane, thereby coming into contact with the substrate. The indentation *vs* force curves exhibited breakthrough events^{23,34,41} where the jump-through distance (noted d) was assimilated as the bilayer's thickness³⁴. The limitations of this measurement were discussed elsewhere⁴² and efforts were taken to regard bilayer compression. Fig.3A and C show three examples of force-distance curves for each type of lipid bilayer. The d mean values obtained were 3.91 ± 0.46 nm, and 4.93 ± 0.47 nm for DOPC and DPPC bilayers, respectively. This thickness difference between fluid and gel phases was perfectly detected by AFM spectroscopy, in agreement with previous works^{25,43}. In the literature, Nagles and Tristram-Nagles⁴⁴ also determined the thicknesses of DOPC and DPPC fully hydrated bilayers using

1
2
3 298 XRD and obtained a value of 3.6 nm for DOPC in the fluid phase and of 4.4 nm for DPPC in
4
5
6 299 the gel phase. It should be noted that DOPC has two unsaturated 18 hydrocarbon chains and
7
8
9 300 DPPC has two fully saturated 16 hydrocarbon chains (Fig1A). Unsaturation is the main
10
11 301 reason that adversely affected chain elongation and molecular packing⁴⁵, making DPPC
12
13
14 302 bilayers more ordered and thicker than DOPC bilayers at room temperature.
15
16
17 303 Noteworthy, the value of the force at which the SLB ruptured (i.e., the breakthrough force)
18
19
20 304 was higher for DPPC (2-3 nN) than for DOPC (<1 nN), in agreement with their respective
21
22 305 phase states⁴⁶⁻⁴⁸. The lower absolute values found in the present study may be accounted for
23
24
25 306 the lower ionic strength and the sharper AFM tip (radius of MNSL tip ~2 nm) in comparison
26
27
28 307 to previous works.

308 **3.3.2. Mechanical properties of DOPC or DPPC liposomes:**

309 In this work, we show that AFM spectroscopy could be used to discriminate and compare the
310
311 mechanical properties of very small liposomes (~150 nm) in different phase states.
312
313 Calculations of the Young modulus E and bending modulus k_C , based on the shell theory
314
315 model, were done on DOPC or DPPC liposomes respectively in fluid or gel phase. In order to
316
317 limit the plastic deformation, force distance curves were recorded over 100 nm distance with a
318
319 set point of 200 pN maximal force. Typical examples are shown in Fig. 3 B and D. In these
320
321 conditions, the approaching and retracting curves were superimposed, demonstrating the
322
323 elastic behavior of the membrane (not shown). The tip-membrane contact was defined as the
324
325 point where significant positive slope appeared. According to the shell theory developed by

Reissner⁴⁹ then Fery et al.^{16,50}, the Young modulus E of thin-shelled spherical micro-capsule under a point load scales with the bilayer's stiffness, k , which was deduced from the slope of the linear region of each force curve after the tip-membrane contact, i.e. in the small deformation region (Fig 3.B and D). As k strongly depends on the size of the individual liposomes²¹, it has to be normalized by the local radius of curvature R_c of the individual liposomes¹⁶ to describe their mechanical properties. Calculation of E requires the bilayers' stiffness k , the local radius of curvature R_c (see section 2.7.1), the bilayer's thickness d (Table1) and the Poisson ratio ν , taken as 0.5:

$$E = \frac{1}{C} \frac{k R_c \sqrt{3(1 - \nu^2)}}{4d^2} \quad (3)$$

In equation 3, C is a coefficient that accounts for the double deformation of an adsorbed shell object, such as liposomes, upon indentation by the AFM tip. Indeed, whereas membrane deformation occurs at the contact point between the tip and the liposome, simultaneous deformation also occurs at the contact area between the liposome and the substrate⁵¹. In their recent paper, Bery et al.⁵² produced calculations for a correction factor, C , to be applied as a function of the relative radii of the tip (20 nm) and liposome, and of the shell thickness relative to the radius of the liposomes (Table 1). Since that dimensions were similar for both the DOPC and DPPC liposomes, C was ~ 0.55 for both types of liposomes.

In another way, the mechanical properties of liposomes can be also represented by the bending rigidity k_C , which is expressed in terms of the same parameters and is also common in the literature:

$$k_c = \frac{Ed^3}{12(1-\nu^2)} \quad (4)$$

Calculation of the Young's modulus, regardless of liposome size, showed that the DPPC liposome membranes (L_β) $E = 116 \pm 45$ MPa were significantly more elastic at 20°C than DOPC liposome membranes (L_α) which exhibited a lower value of $E = 13 \pm 9$ MPa (Fig.4.A and B; $p < 0.05$). Accordingly, the liposome membranes composed of DPPC were also stiffer with $k_c = (15.5 \pm 6) \times 10^{-19}$ J (360 k_B T) than those composed of DOPC with $k_c = (0.9 \pm 0.6) \times 10^{-19}$ J (22 k_B T) (Fig.4.C and D; $p < 0.05$). To verify that electrostatic repulsion was not implicated in the force curves near the contact point, we compared the results acquired on DPPC liposomes with varying surface charge, taken as the zeta potential and measured as described in Makino et al.⁵³. The DPPC liposomes were positively charged with a zeta potential of 18 mV in PIPES buffer (ionic strength $I=0.09$); and barely charged with a zeta potential of 0.11 mV in PBS buffer (14 mM KH_2PO_4 , 200 mM Na_2HPO_4 , NaCl 1.36 M, KCl 20 mM; $I=1.99$; pH= 7.2). The Young's modulus showed a mean value of $E = 120 \pm 39$ MPa in PBS buffer and no significant difference was found between the Young moduli values obtained in the two buffers ($p > 0.05$). This result showed that force measurement of DPPC membrane was not influenced by electrostatic interaction between the AFM probe and the liposomes.

The Young modulus was also estimated using the R_c of the whole liposome, which involves the two parameters H and W (equation A.1). The results showed that the elasticity of DPPC

was higher (183 MPa) than that obtained by local R_c (116 MPa), whereas E was not significantly changed for DOPC. With either methods of R_c calculation, the results therefore showed that AFM indentation was able to detect significant differences in the elasticities of the two membranes depending on their fluid or gel phase state. However, the quantification of the mechanical properties was found very sensitive to calculation of R_c and to the liposome geometry. For these reasons, we chose to compare the liposomes using the method based on the local R_c using Gwyddion in order to avoid any effect due to the form adopted by the liposomes upon adsorption.

In conclusion, the structural differences between the fluid-phase DOPC and gel-phase DPPC bilayers as evidenced by DSC and XRD, induced by the unsaturation of the acyl chains (Fig1), resulted in significant difference in their respective mechanical responses. Hence, AFM force spectroscopy proved a sensitive method to compare the mechanical properties of small liposomes with different lipid compositions and phase states. Only few reports exist that have evaluated these mechanical parameters for similar systems of lipid membrane in 3D, especially for DOPC or DPPC using AFM spectroscopy (Table 2). Of all these studies, only Liang et al.²¹ used AFM spectroscopy comparatively, on liposomes with increasing addition of cholesterol. Liang et al.²¹ obtained Young's modulus of 1.97 ± 0.75 MPa, for liposomes in the fluid phase composed of egg PC (mixture of saturated and unsaturated polar lipids; mostly in the form of SOPC – stearoyl-oleoyl-phosphatidylcholine). Using an optical method, Meleard et al.⁵⁴ and Duwe et al.⁵⁵ respectively obtained bending rigidities of $1.27 \pm 0.09 \times 10^{-7}$

¹⁹J (31 k_BT) or 1.15×10^{-19} J (28 k_BT) for liposomes composed of the saturated polar lipid DMPC (1,2-dimyristoyl-sn-glycero-3-phosphocholine) in fluid phase at 40°C ($T_m = 24^\circ\text{C}$). Rawicz et al.⁴⁵ found values of $\sim 0.9 \times 10^{-19}$ J for bilayers of various synthetic 18:1 phospholipids. Another group, Hantz et al.⁵⁶ used the osmotic swelling method and found values of the Young's modulus of 15 MPa for DOPC liposomes in the fluid phase at 20°C. Delorme and Fery¹⁶ obtained Young's moduli values of 110 ± 15 MPa for DPPC liposomes in the gel phase. Taking only account of the phase state conditions, the values available in the literature (Table 2) are in the same order of magnitude in comparison to the results showed in this work. Differences between studies could be attributed mainly to the nature of the lipids (carbon chain length, number of unsaturation), the temperature, the chosen technique or, for indentation studies, the mathematical model chosen for the calculation of R_c or E ^{57,58}. The presented results show that AFM indentation of liposome is a sensible method for comparison between different lipid membranes.

For the sake of comparison with the SUV (tridimensional organization), the elasticity of DPPC or DOPC membranes was calculated on the SLB (two dimensional organization) using AFM load curves performed in the same conditions as for the breakthrough force measurement. Only a larger MLCT probe was used for better sensibility. By attempting the fit of equation (5), the Young's moduli (noted E_{SLB}) and bending modulus (noted k_{C-SLB}) were calculated using the classical Hertz model:

$$F = \frac{4E_{SLB}\sqrt{R_{tip}}\delta^{\frac{3}{2}}}{3(1-\nu^2)} \quad \text{or} \quad E_{SLB} = \frac{3k(1-\nu^2)}{4\sqrt{R_{tip}}\delta} \quad (5)$$

394 For which corresponds a bending modulus:

$$k_{C-SLB} = \frac{E_{SLB}\delta^3}{24(1-\nu^2)} \quad (6)$$

395
396 Where the parameters are the same already cited for liposome membranes. In these equations,
397 δ is the indentation distance and R_{tip} is the nominal radius of AFM MLCT tip (~20 nm).
398 The use of contact mechanics using the Hertz model on SLB is limited by the effect of
399 confinement of the sample between the tip and the underlying substrate^{59,60}. Furthermore,
400 lipid bilayers are not anisotropic materials. However, previous investigations suggested that
401 this calculation yet has comparative interest^{25,61}. On SLBs, the Young modulus (E) of DOPC
402 was found to be 27 ± 8 MPa with a corresponding bending modulus $k_C = (0.88 \pm 0.25) \times 10^{-19}$ J,
403 while the E and k_C of DPPC were found to be 31 ± 12 MPa and $(2.03 \pm 0.79) \times 10^{-19}$ J,
404 respectively. Therefore, the E and k_C parameters of DPPC and DOPC were less distinct when
405 measured on SLB than on SUV (Table 2). Meanwhile, more dispersed E values were reported
406 in the literature for SLBs than for liposomes, thereby indicating the higher sensitivity of this
407 measurement upon experimental conditions in the case of SLB^{25,61,62} (Table 2). To conclude,
408 it is showed that membranes in the gel phase were more elastic and stiffer than the
409 membranes in fluid phase regardless the lipid organization (2D or 3D). However, the values
410 of E and k_C were more robust when measured on liposomes than on SLBs, where the presence

of the solid support affected the results depending on the indentation distance²⁵. These comparisons show that liposomes are adequate systems to determine the elastic properties of lipid membranes. On the other hand, measurement of the breakthrough force is relevant for SLBs.

The structure of molecules and the intermolecular interactions that lead lipid molecules to self-assembly in bilayers, have a significant impact on the rigidity of these bilayers^{63,64}. The elasticity of the membrane allows it to accommodate strain without failure, which is essential in many applications where the membrane need to resist shear stress, e.g. in transdermal application, in blood vessels, the epithelial cells of the gastrointestinal tract, etc. The hydrophobic interactions between the lipid molecules, in particular Van der Waal interactions, are the major responsible of the fluidity and the rigidity of the membrane. The double bond in cis conformation interferes with hydrocarbon chain packing and destroys the cooperativity of the chain interactions in the bilayer^{65,66}.

The presence of this double bonds reduces the hydrophobic interactions by increasing the distance between the hydrophobic moieties which decreases the stiffness of membrane⁴⁵.

IV. CONCLUSION:

The nano-indentation of DOPC and DPPC liposomes by AFM probe at low force load was able to provide local and discriminant information on the elastic properties of bilayer membranes in 3D organization without plastic deformation. The Young's moduli E and bending rigidity values k_C of gel phase DPPC membranes is significantly higher than that of

fluid phase DOPC ones at 20°C, in agreement with their different phase state. The perspective of this work is to investigate the mechanical properties of biological membranes with complex chemical composition and fluid/gel phase coexistence. Thanks to the high lateral resolution of AFM, it is expected that phase separation and correlated nanomechanical contrast may be measured directly on model liposomes or even biological vesicles.

V. ACKNOWLEDGMENTS

The Asylum Research MFP3D-BIO atomic force microscope was funded by the European Union (FEDER), the French Ministry of Education and Research, INRA, Conseil Général 35 and Rennes Métropole. The doctoral fellowship of author Et-Thakafy was funded by INRA CEPIA and Région Bretagne under the grant ARED 8806.

VI. APPENDIX:

The Young modulus values were also obtained using radius of curvature R_C of the whole individual liposomes. It was calculated using H and W of the individual liposomes⁶⁷, as:

$$R_C = \frac{0.25W^2 + H^2}{2H} \quad (A.1)$$

The mechanical data obtained from literature were expressed either as the Young modulus E , the bending rigidity k_C or both. To complete and compare literature information in table 2; we used the following equations to provide both parameters for each cited reference:

For liposome (shell model):

$$k_C = \frac{E d^3}{12(1 - \nu^2)} \Rightarrow E = \frac{12(1 - \nu^2)k_C}{d^3} = \frac{9k_C}{d^3} \quad (A.2)$$

For supported lipid bilayer (Hertz model):

$$k_{C-SLB} = \frac{E_{SLB} d^3}{24(1 - \nu^2)} \Rightarrow E_{SLB} = \frac{24(1 - \nu^2)k_{C-SLB}}{d^3} = \frac{18k_{C-SLB}}{d^3} \quad (A.3)$$

E : Young modulus

k_C : bending rigidity

ν : Poisson coefficient (0.5)

d : membrane thickness

For the publication where the membrane thickness not shown, the following values were used

to calculate the elasticity or the bending rigidity:

$d(\text{DMPC}) = 3.6 \text{ nm}$ ⁴⁴

$d(\text{DOPC}) = 3.9 \text{ nm}$ (present work)

TABLES

Table1: Geometrical parameters of dioleoylphosphatidylcholine (DOPC) or dipalmitoylphosphatidylcholine (DPPC) liposomes and their corresponding membrane thicknesses. The height (H) and width (W) mean values were measured using the cross section of AFM images of the liposomes and used to calculate the volume of the adsorbed liposomes,

663 from which the mean diameter of a sphere of equivalent volume was deduced (Eq.2). The
664 mean values of DOPC and DPPC membrane thicknesses were measured using the jump
665 distance d from breakthrough force curves (n=30) recorded in PIPES/NaCl/CaCl₂ buffer, pH
666 6.7 at 20°C.

Lipid	Mean height H of liposomes by AFM (nm)	Mean width W of liposomes by AFM (nm)	Mean diameter of equivalent sphere by AFM (nm)	Mean diameter of liposomes by DLS (nm)	Membrane thickness by AFM (nm)
DOPC	59 ± 27	310 ± 97	150 ± 90	120 ± 69	3.91 ± 0.41
DPPC	151±48	448 ± 154	296 ± 88	132 ±73	4.93 ± 0.47

Figure 3: AFM indentation measurement on DOPC (dioleoylphosphatidylcholine, in blue) or DPPC (dipalmitoylphosphatidylcholine, in red) liposomes adsorbed on silicon substrate. (A) and (C) show the breakthrough force curves obtained as a result of tip penetration into DOPC or DPPC supported lipid bilayers, respectively. The average bilayer thickness value d was measured from the jump-through distance ($n=50$). (B) and (D) show typical force curves acquired during indentation of, respectively, DOPC or DPPC liposomes in the elastic regime; in order to infer the bilayer stiffness k from the slope after tip-membrane contact. For the sake of clarity, the force curves are shifted along the Y axis. All measurements were recorded in aqueous PIPES/NaCl/CaCl₂ medium at pH = 6.7 and at 20°C.

Figure 4: Distributions of the Young moduli E and of the bending rigidity k_C , independent of liposome size, of DOPC ($n=108$) and DPPC ($n=71$). (A) and (C) show the superposition of both DOPC and DPPC frequency distributions for E and k_C , respectively. (B) and (D) show
