Abstract

A uniaxial experiment is performed on ultra-thin specimen made of 17-7 precipitation hardened stainless steel. An anti-wrinkling setup allows for the characterization of the mechanical behavior with Integrated Digital Image Correlation (IDIC). The result shows that a single uniaxial experiment investigated via IDIC possesses enough data (and even more) to characterize a complete anisotropic elastoplastic model.

Résumé

De l'identifiabilité du modèle de Hill-1948 à l'aide d'un seul essai de traction uniaxiale. Un essai de traction uniaxiale est conduit sur un échantillon en acier inoxydable 17-7 à durcissement structural. Un montage anti-plissement permet la caractérisation du comportement mécanique par corrélation d’images numériques intégrée (CINI). Il est montré que ce seul essai analysé par CINI possède assez d’information (voire plus) pour une identification complète du modèle de plasticité anisotrope.

Key words: Digital Image Correlation (DIC); Full field measurements; Identification; Plastic anisotropy

Mots-clés : Corrélation d’images numériques (CIN); Mesures de champ; Identification; Anisotropie plastique

1. Introduction

For engineering design purposes, von Mises’ [1] criterion is commonly used and gives satisfactory results. However, industrially-manufactured materials require plastic anisotropy to be accounted for. For instance, sheet metal forming calls for anisotropic plasticity models. Numerous authors have actively discussed their characterization. Whiteley [2] and Lloyd [3] investigated the importance of directionality in deep drawing of sheet steel and so-called pressed-metals. Lankford et al. [4] proposed an experimental ratio to characterize plastic anisotropy. Hill [5] and Dorn [6] introduced the first models to describe anisotropic plastic flow. These models have been extended to describe more complex constitutive laws [7]. Many developments have followed since these early propositions. However, one of the standard and most widely used model in nowadays commercial finite element codes [8] still is Hill’s original proposition (i.e., the so-called Hill-1948 model [9]).

The calibration of such models calls for several tensile tests, at least in three directions (i.e., generally 0°, 90°, and 45° with respect to the rolling direction [10]). It is worth noting that more complex test configurations are also used (e.g., plain strain tensile test, shear test, experiment on cross-shaped samples, bulge test) even though very few of them are standardized. Most of these tests consider zones where the strain and stress states are uniform so that simple extraction techniques are considered to determine the sought quantities. With the development of full-field measurement techniques [11], another route consists of analyzing and designing the test as being fully heterogeneous [12].

The present study aims at identifying an anisotropic plasticity law, investigating Hill-1948 quadratic yield function via Integrated-DIC [13,14,15,16,17,18,19]. The key feature consists in analyzing a single sample made of ultra-thin precipitation hardened steel and tested in uniaxial tension. A sensitivity analysis is performed to assess the identifiability of an anisotropic yield surface coupled with linear kinematic hardening and isotropic elasticity. It will be shown that seven material parameters can be evaluated even though the sample geometry remains very simple.

2. Methodological framework

2.1. Investigated constitutive law

In the following, linear and isotropic elasticity (with Young’s modulus $E$ and Poisson’s ratio $\nu$), and linear kinematic hardening with a quadratic yield criterion [5] are coupled. The total strain rate $\dot{\varepsilon}$ is written in terms of elastic and plastic strain rates $\dot{\varepsilon} = \dot{\varepsilon}_{el} + \dot{\varepsilon}_{pl}$ where $\dot{\varepsilon}_{el}$ is the elastic strain rate tensor and $\dot{\varepsilon}_{pl}$ the plastic strain rate tensor. As a first approximation, a linear kinematic hardening model is chosen for the back-stress rate [20] in which $C$ is the hardening modulus. Last, the quadratic [5] anisotropic yield criterion is expressed in terms of rectangular Cartesian stress components as

$$f(\sigma) = \sqrt{H_1(\sigma_{22} - \sigma_{33})^2 + H_2(\sigma_{33} - \sigma_{11})^2 + H_3(\sigma_{11} - \sigma_{22})^2 + 2H_4\sigma_{23}^2 + 2H_5\sigma_{31}^2 + 2H_6\sigma_{12}^2}$$  \hspace{1cm} (1)

where $H_i$ are constants expressed with the normal yield stress ratios ($R_{11}$, $R_{22}$, $R_{33}$) and those in shear ($R_{12}$, $R_{23}$, $R_{31}$) both with respect to the axes of anisotropy [9]

$$H_1 = \frac{1}{2} \left( \frac{1}{R_{22}^2} + \frac{1}{R_{33}^2} - \frac{1}{R_{11}^2} \right), \quad H_2 = \frac{1}{2} \left( \frac{1}{R_{33}^2} + \frac{1}{R_{11}^2} - \frac{1}{R_{22}^2} \right), \quad H_3 = \frac{1}{2} \left( \frac{1}{R_{11}^2} + \frac{1}{R_{22}^2} - \frac{1}{R_{33}^2} \right), \quad H_4 = \frac{3}{2R_{23}^2}, \quad H_5 = \frac{3}{2R_{31}^2}, \quad H_6 = \frac{3}{2R_{12}^2}$$

The computations being two dimensional, $R_{31}$ and $R_{23}$ are insensitive and set to 1 hereafter (and hence $H_4 = H_5 = 3/2$). One of the in-plane parameters must be chosen to decorrelate its value from the yield stress $\sigma_y$ (i.e., $H_1$ is set to 1/2 in the sequel). Therefore, only three additional material parameters, i.e., $H_2$, $H_3$, and $H_6$, remain to be determined when plastic anisotropy is accounted for. To conclude, 7 parameters (i.e., $E$, $\nu$, $\sigma_y$, $C$, $H_2$, $H_3$, and $H_6$) need to be calibrated with the chosen model.

2.2. Integrated-DIC

The calibration of the material parameters $\{p\}$ is performed via Integrated Digital Image Correlation where the unknowns are no longer kinematic degrees of freedom but the sought constitutive parameters themselves. Integrated-DIC is a global technique that registers an image $f$ in the reference configuration and a series of $N_t$ pictures $g$ in the deformed configurations. Assuming gray level conservation, the inverse
problem is solved by minimizing the sum of squared differences between the deformed image corrected by the trial displacement \( u(x, t, \{ p \}) \) and the reference image

\[
\chi^2_f(\{p\}) = \frac{1}{2\gamma_f^2 N_t N_\Omega} \sum_t \sum_\Omega ((g(x + u(x, t, \{ p \}), t) - f(x))^2
\]

with respect to \( \{ p \} \). In this expression \( \Omega \) denotes the Region of Interest (ROI), \( N_\Omega \) its area in terms of the number of pixels it contains, \( x \) any considered pixel, and \( \gamma_f = 323 \) gray levels is the standard deviation (i.e., 2\% of the dynamic range of \( f \)) of the white noise assumed to affect each image independently (including the reference one, which is responsible for the factor of \( 1/2 \) coming as a multiplicative term in this functional). The load is also of importance for the identification because it increases the number of the measured quantities and as a consequence diminishes the relative uncertainty by enhancing the material parameter sensitivities [12]. Thus, a second objective function, \( \chi^2_F \), is introduced

\[
\chi^2_F = \frac{1}{N_F N_\Omega \gamma_F^2} \{F_m - F_c(\{p\})\}^\dagger \{F_m - F_c(\{p\})\}
\]

where \( \{F_m\} \) are the measured reaction forces and \( \{F_c(\{p\})\} \) the computed levels that depend on the chosen material parameter set, \( N_F \) the number of load cells, and \( \gamma_F \) the load variance (i.e., 100 N in the present case). The identification, which is based upon both observables (i.e., gray levels and reaction forces), is achieved by minimizing the global functional \( \chi^2(\{p\}) \)

\[
\chi^2(\{p\}) = \frac{N_\Omega}{N_\Omega + N_F} \chi^2_f(\{p\}) + \frac{N_F}{N_\Omega + N_F} \chi^2_F(\{p\})
\]

where the DIC and reaction force functionals have been introduced in Equations (2) and (3) respectively. The choice for the specific weight is issued from a Bayesian approach whereby the noise characteristics imposes the appropriate weights to be given to quadratic differences [12]. In particular, quadratic differences are to be evaluated with a metric equal to the inverse noise covariance.

When nonlinear behaviors are investigated, the dependence of the displacement field with the material parameters is nonlinear as well. Consequently, sensitivity fields (i.e., displacement and reaction force derivatives with respect to the sought parameters) are computed via finite element simulations. In the present case the commercial (implicit) finite element code used is Abaqus standard [9]. It is driven by the measured displacements (via FE DIC) on the upper and lower edges of the considered region of interest to compute the displacement fields and reaction forces. If the FE mesh is finer in Integrated DIC in comparison to DIC, the measured displacements on the coarser mesh are interpolated on the finer mesh.
2.3. Sensitivity analysis

To probe the identifiability of the 7 parameters, a sensitivity analysis is carried out. Consequently, the Hessian of the Integrated DIC code is analyzed [12]. Figure 1(a) shows the global Hessian \((H_{IFDIC})\) of the IDIC procedure. The material parameters having the largest influence are \(H_1, H_2,\) and \(H_3\) and account for the anisotropic plasticity behavior (\(H_1\) is analyzed to show its correlations with other parameters but for identification purposes its value is kept equal to one half). This result shows that a uniaxial experiment enables for the characterization of an anisotropic behavior. It also indicates that this behavior must be accounted for when plastic anisotropy is suspected to occur. Figure 1(b) shows that the Poisson’s ratio is correlated to \(H_1, H_2,\) and \(H_3,\) and explains why it is necessary to have a model that separates both contributions from the Poisson’s ratio and the anisotropic coefficients. Once the lowest eigen value of the complete Hessian has been taken out, its condition number is of the order of \(10^6,\) which is not too high given the number of remaining parameters. From this analysis, it is concluded that the 7 parameters are identifiable.
Figure 1. Global Hessian (a) and its corresponding correlation matrix (b) for the investigated model (i.e., \( \{ p \} = \{ E, \nu, \sigma_y, C, H_1, H_2, H_3, H_6 \}^T \)). The absolute value of the Hessian is used to allow for a logarithmic scale.

3. Parameter identification

The present study investigates the mechanical behavior of a 70-\( \mu \)m thick sheet of precipitation hardened stainless steel (17-7 PH grade) in TH1050 condition. The manufacturer [21] assessed the elastic properties of the studied material. The specimen is loaded in a servo-hydraulic tension/compression testing machine (see Figure 2(a)). The experiment consists of three loading/unloading cycles in a displacement controlled mode with increased displacement amplitudes for each new cycle. The unloading phases are stopped when the measured load reaches 10 N to avoid compression. The maximum von Mises equivalent strain is of the order of 8 \%. 14-bit gray scale images are captured with a digital camera (pc0.pixelfly) and a telecentric lens. The effective magnification is 70 \( \mu \)m per pixel. Last, the load measurements and the image acquisitions are synchronized.

The main experimental challenge concerns the specimen thickness that prevents grooved grips to be used. The solution consists in bonding the specimen ends to flat-surface aluminum alloy tabs with a 3M Scotch-Weld Structural Adhesive Film AF 126 [22]. Residual wrinkles are generated during this process near the edges. To maintain the surface flat in the center region (crucial to perform 2D-DIC analyses) an
anti-wrinkling device is designed (see Figure 2). It consists in holding the specimen between two Plexiglas sheets fastened with four screws. A very small gap is left between the Plexiglas sheets to minimize as much as possible the effects of friction on the tested sample. To perform DIC analyses a random speckle pattern is applied on the monitored surface and no paint loss was observed during the test, thereby validating the hypothesis of negligible friction induced by the anti-wrinkling device. Figure 2 shows at the last experimental time step the measured (b) and identified (c) displacement fields associated with three-noded triangular meshes with linear interpolation (T3). For DIC, the mesh size is of the order of 60 pixels, and 40 pixels for Integrated DIC.

Figure 2. (a) Uniaxial specimen with dedicated anti-wrinkling device. (b) DIC and (c) IDIC displacement fields $u_x$ at the last experimental time step with two mesh sizes; (c) also shows the area that will be used to assess the Lankford coefficient. The displacements are expressed in pixels (1 pixel $\leftrightarrow$ 70 $\mu$m)

Figure 3(a) shows the normalized gray level residuals (i.e., $\chi_f$) at each time step for DIC and IDIC analyses. Prior to starting the experiment, 10 images and load measurements are acquired to assess the
uncertainties. Then, the experiment starts and the residual increases to roughly four times the noise level. The DIC residual remains relatively constant over the experiment. Conversely, the IDIC residuals are on average higher than DIC residuals. Let us stress that DIC is based on a number of degrees of freedom equal to 600 per image, or 114,600 for the entire experiment, whereas the IDIC approach has no more than 7 degrees of freedom. This very drastic reduction incorporates many constraints due to a priori assumption on the material behavior. The difference in residuals from DIC to IDIC is an indication of the model error that is due to the specific chosen constitutive law. Once the elastic regime ends ($t \geq 20$ s), the IDIC residuals increase and exceed the DIC residuals. This result shows that the assumption of a constant anisotropic behavior, i.e., constant anisotropic coefficients as a function of the plastic strain, is not totally consistent with the experimental data. Similarly, Figure 3(b) shows that the load levels are consistent in the elastic regime and gradually degrade in anisotropic plasticity.

![Figure 3](image.png)

**Figure 3.** (a) Gray level residual history $\chi_f(t)$ for DIC and IDIC. (b) Applied and computed reaction force history

Table 1 gathers the assessed material parameters for the studied constitutive law. Their initial values ($\{p_0\}$) are chosen according to literature data [21,23]. The initial and last values of the residuals are also shown (1st — last) for the investigated law plus one identification with a coarser mesh (referred to as IDIC*). All the parameters converge to a stabilized level while the residuals $\chi$ for each laws are minimized. First, the IDIC residual is greater than the DIC residual obtained with a coarse mesh (i.e., the one used to measure the boundary conditions) but lower than the IDIC* residual obtained on the same mesh. This is an indication that model errors occur. It proves that refining the mesh (Figure 2) can enhance
the identification quality by decreasing the gray level residuals. This mesh difference also explains why the DIC residual is larger than the IDIC residuals during the first time steps \((t \in [10; 20] \text{ s})\). The load residuals also decrease.

Table 1
Identified parameters and identification residuals via IDIC over the entire loading history cycle (IDIC\(^*\) corresponds to the DIC mesh and “1\(^{st}\) — last” corresponds to the first and last value of the residuals)

The lowest global residual corresponds to 7 times the noise level, which indicates that the model does not fully capture all the experimental behavior. Figure 4 shows the displacement field residual for the transverse component (i.e., difference between the IDIC and DIC displacement fields). The displacement difference is not noise (i.e., measurement uncertainty) but rather a smooth component that is not totally accounted for by the model. This is a clear manifestation of model error. The short wavelength component close to the upper edge is believed to be due to small wrinkles.
The Lankford coefficient is an indicator used to describe the anisotropic plasticity behavior of sheet metals [10]. It corresponds to \( r = \epsilon_{33}^p / \epsilon_{11}^p \) where \( \epsilon_{11}^p \) is the transverse plastic strain, \( \epsilon_{33}^p \) the out-of-plane plastic strain. This analysis is performed in the central area (see Figure 2(c)) of the specimen and the reported strains are the corresponding mean values. Figure 5 shows the Lankford coefficients both for DIC and IDIC results. For DIC analyses, the elastic strains are evaluated from the applied load and the knowledge of the elastic properties of the alloy. Incompressibility is assumed for the plastic strains to evaluate \( \epsilon_{33}^p \). The coefficient converges for both cases to a constant value as the level of plastic strain increases. The asymptotic value (i.e., about 2) is consistent with literature data of cold-rolled stainless steel [24]. Second, the model does not fully capture the experimentally observed anisotropy in the early stages of plasticity. This result shows that even if the identification of the anisotropic coefficients has been achieved, the assumption of a constant anisotropic behavior is an approximation. This is consistent with the fact that the IDIC residuals are higher at the end of cycle 1 and the beginning of cycle 2 (see Figure 3).

It is to be emphasized that using full field measurements allows for the calibration of the entire set of parameters using a single experiment. Such a conclusions was also drawn for a thicker sample made of
aluminum alloy [25]. It also gives access to an evaluation of a significant model error (based on the value of the final residuals being well above 1, see Table 1), and it provides in addition an assessment of the deviation in the observed and fitted strains through the Lankford ratio, which may help enriching the constitutive law (say with an evolving anisotropy) in order to reduce the model error.

Figure 5. Lankford ratio evaluated from DIC and from the identified anisotropic elastoplastic anisotropic

4. Conclusion

The identifiability of the Hill-1948 model has been investigated with Integrated Digital Image Correlation for a uniaxial test on ultra-thin sheet made of precipitation hardened stainless steel. A dedicated anti-wrinkling system was designed and employed to prevent non uniform out-of-plane displacements while loading and unloading the specimen. The identification is performed over the entire history accounting for three loading/unloading cycles. The sensitivity analysis proves that the anisotropic yield criterion can \textit{a priori} be quantitatively evaluated. It is shown \textit{a posteriori} that it is possible to determine all material parameters for the in-plane anisotropic plastic model in a \textit{single} uniaxial experiment thanks
to full-field measurements. Moreover, the same experimental procedure is rich enough to indicate a model error and provides some insight into directions for enrichment of the constitutive law to better describe the experiment.
