Abstract: This paper emphasizes several dynamical aspects of a quadrotor induced by propellers inertia, especially when its rotors are tilted or asymmetrically distributed around its body. To achieve this, a simplified, linear model is established for a generic quadrotor and successively applied in three cases: a flat and symmetric quadrotor, a V-shaped quadrotor and finally an asymmetric quadrotor. The results are illustrated via numerical simulations.

Keywords: UAVs, quadrotors modelling.

1. INTRODUCTION

The use of quadrotors has dramatically increased during the last decade, with the rise of consumer quadrotors. These drones notably have applications in video making, but also in industries, such as construction sites management, agriculture monitoring or infrastructure inspection.

The most common quadrotor configuration is composed of four fan propellers, symmetrically disposed around the center of mass of the drone, alternating clockwise and anti-clockwise directions of rotation, and all pointing toward the vertical axis of the drone. This configuration is often referred to as an ‘X4’ configuration. The modelling and control of X4 quadrotors has been intensively studied, in such works as Shapovalov et al. (2014), Hamel et al. (2002), Bangura and Mahony (2014), Pounds et al. (2006), etc.

With four propellers to control their six degrees of freedom (DOF) of motion, quadrotors constitute underactuated systems. Consequently, these 6DOF cannot be controlled independently. Nevertheless, the actions of the propellers on the drone can be intuitively decoupled on an X4 quadrotor, which constitutes one advantage of this configuration.

However, with such a configuration, the dynamics on the yaw axis is usually inferior to those on the roll and pitch axes. This is due to the rotation around the yaw axis being mostly controlled using the propellers drag torques, while their lift is used for pitch and roll control, through the leverage it induces. Depending on the configuration, the latter tends to be 10 to 100 times stronger than the drag torques, resulting in weaker dynamics on the yaw axis.

A solution to balance these dynamics is to tilt the propellers axes in order to have a leverage induced by the lift on the yaw axis, too. This can be achieved by actuating the orientation of the propellers, as in Moutinho et al. (2015), or by using non-X4 configurations. In Hossain et al. (2012), an Y4 (‘V-tail’) configuration is studied, with the rear propellers tilted in a V shape. Studies on a Lynxmotion Hunter V400 frame, a popular V-tail frame among hobbyists, has also been lead recently in Belllocchio et al. (2016).

Furthermore, when adding payloads on the drone, the center of mass could be moved and the action of the different propellers could become asymmetric. Such an asymmetry can also be a matter of design, for instance, in order to achieve a better aerodynamic profile.

The main contribution of this paper consists in analyzing the effects of the propellers orientation and asymmetries on a V-shaped quadrotor. More specifically, we highlight a nonminimum phase behaviour on the pitch dynamics due to the action of propellers inertia, appearing when the V-angle increases. In addition, for asymmetrical drones, coupling terms can arise between the different axes.

Notation. In the sequel, $s_x$, $c_x$, and $t_x$ are used to denote $\sin x$, $\cos x$, and $\tan x$, respectively.

2. QUADROTOR MODELLING

We consider the movement of a quadrotor equipped with four propellers in the inertial reference frame $\mathcal{R}_W = (O, x_W, y_W, z_W)$. We choose $\mathcal{R}_B = (G, x_B, y_B, z_B)$ as the body-fixed frame, with $G$ the center of mass of the quadrotor (Fig. 1). We assume $z_W = z_B$ in case of hovering without perturbation. The quadrotor and its propellers are supposed to be rigid. The position of the center of mass in the inertial frame is given by $\mathbf{r} = x x_W + y y_W + z z_W$, and its speed in the inertial frame is denoted by $\dot{\mathbf{r}} = \dot{x} x_W + \dot{y} y_W + \dot{z} z_W = v x_B + w y_B + u z_B$. We use Euler angles $(\varphi, \theta, \psi)$ - convention ZYX - to describe the attitude of the drone, and thus we define the rotation matrix $R$, between $\mathcal{R}_W$ and $\mathcal{R}_B$.

* The first author is a first year PhD student. This work was supported by Parrot Drones.
Denoting by $\Omega_{B/W} = p \mathbf{X} + q \mathbf{Y} + r \mathbf{Z}_B$ the rotation speed vector of the drone in the inertial frame, the following expression holds

$$\begin{bmatrix} \dot{\varphi} \\ \dot{\theta} \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \begin{bmatrix} s_\varphi \theta \\ c_\varphi \theta \end{bmatrix} + \begin{bmatrix} 0 \\ c_\varphi \end{bmatrix} \begin{bmatrix} \dot{\varphi} \\ \dot{\theta} \end{bmatrix}$$

For small $\varphi$ and $\theta$ angles, (1) is equivalent to $(\dot{\varphi}, \dot{\theta}) \approx (p, q)$. Finally, let $m$ be the total mass of the quadrotor and $\mathbf{J} = \text{diag}(J_x, J_y, J_z)$ its inertia tensor in $\mathcal{R}_B$.

We will next consider the propellers, the gravity and the body drag influence in order to derive a linear model for the system dynamics near the hovering equilibrium.

**Propellers.** The drone is equipped with four propellers, $(p_1, p_2, p_3, p_4)$. Denoting by $P_i$ the center of mass of the $i$-th propeller, its position in the body-fixed frame $\mathcal{R}_B$ is $\mathbf{G}_i = l_{x_i} \mathbf{x}_B + l_{y_i} \mathbf{y}_B + l_{z_i} \mathbf{z}_B$. The rotation speed vector of the propeller $p_i$ in $\mathcal{R}_B$ is $\mathbf{w}_i = \omega_i \mathbf{z}_p$, with $\omega_i > 0$. The orientation of $\mathbf{z}_p$ in $\mathcal{R}_B$ is given by the angles $\psi_i \in [-\pi, \pi]$ and $\theta_i \in [0, \pi]$, as illustrated in Fig. 2.

A quadratic model is chosen for the lift force $\mathbf{T}_i$ and drag torque $\Gamma_i$ applied on the $i$-th propeller

$$\mathbf{T}_i = \alpha_i \omega_i^2 \mathbf{z}_p, \quad \Gamma_i = \beta_i \omega_i^2 \mathbf{z}_p,$$

with $\alpha_i > 0$ or $\alpha_i < 0$ depending on the orientation of the propeller in $\mathcal{R}_B$, and $\beta_i < 0$. We can linearize (2) near the hovering equilibrium state by defining $\omega_i = \omega_i^t + \delta\omega_i$, with $\omega_i^t$ the rotation speed of the $i$-th propeller when hovering (without any perturbation such as wind or ground effect). This allows approaching

$$\mathbf{T}_i \cdot \mathbf{z}_p \approx T_{0i} + \alpha_i \delta\omega_i, \quad \Gamma_i \cdot \mathbf{z}_p \approx \Gamma_{0i} + b_i \delta\omega_i$$

with $T_{0i} = \alpha_i \omega_i^t l_{z_i}$, $\alpha_i = 2\alpha_i \omega_i^t$, $\Gamma_{0i} = \beta_i \omega_i^t l_{z_i}$, $b_i = 2\beta_i \omega_i^t l_{z_i}$. The leverage induced by propellers lift is then

$$\Gamma_i = \mathbf{G}_i^2 \times \mathbf{T}_i,$$

Let us denote by $J_p$ the inertia of the $i$-th propeller with respect to its rotation axis $\mathbf{z}_p$. The reaction torque applied on the quadrotor via the $i$-th propeller is given by

$$\Gamma_{ri} = -J_p \dot{\omega}_i \mathbf{z}_p,$$

We neglect the gyroscopic torques generated by the propellers, as they are much smaller than those induced by the propellers drag and lift for small rotation speeds of the drone. Since the quadrotor has four propellers, the total force applied by the propellers on the drone is $\sum_{i=1}^{4} \mathbf{T}_i$, and the total torque is $\sum_{i=1}^{4} \Gamma_i + \Gamma_{ri}$. The gravity action on the drone is modeled by a constant force $\mathbf{f}_g = mg \mathbf{z}_W$. For small angles, this expression becomes

$$\mathbf{f}_g \approx -mg \theta \mathbf{x}_B + mg \varphi \mathbf{y}_B + mg \mathbf{z}_B$$

**Body drag.** We can add a simplified linear model of the aerodynamic drag of the quadrotor body around the hovering equilibrium state, as the combination of a force $\mathbf{f}_d$ and a torque $\tau_d$, given by

$$\mathbf{f}_d = -C_x u \mathbf{x}_B - C_y v \mathbf{y}_B - C_z w \mathbf{z}_B$$

$$\tau_d = -C_p x \mathbf{x}_B - C_q y \mathbf{y}_B - C_r z \mathbf{z}_B$$

Thus, with small but constant angles, the drone model reaches a terminal velocity instead of accelerating indefinitely. Close to the hovering equilibrium, the action of body drag torques is reduced, since the rotation speed of the drone is supposed to be small anyway.

**Linear Model.** Applying the fundamental principle of dynamics leads to

$$m \ddot{\mathbf{r}} = \mathbf{f}_g + \sum_{i=1}^{4} \mathbf{T}_i, \quad \mathbf{J} \ddot{\mathbf{w}} = \sum_{i=1}^{4} (\Gamma_i + \Gamma_{ri}) - \mathbf{J} \mathbf{w} \times \mathbf{J}_W$$

At the hovering equilibrium, with (3), the following expression holds

$$0 = mg \mathbf{z}_B + \sum_{i=1}^{4} T_{0i} \mathbf{z}_p, \quad 0 = \sum_{i=1}^{4} \Gamma_{0i} \mathbf{z}_p.$$

For small angular speeds of the quadrotor, the expression (4) can be linearized by neglecting the term $\mathbf{J} \mathbf{w} \times \mathbf{J}_W$. Using (5), it comes

$$m \ddot{\mathbf{r}} = -mg \theta \mathbf{x}_B + mg \varphi \mathbf{y}_B + mg \mathbf{z}_B$$

$$\mathbf{J} \ddot{\mathbf{w}} = \sum_{i=1}^{4} \mathbf{T}_i - \mathbf{J} \mathbf{w} \times \mathbf{J}_W$$

where $(u, v, w) = (u_0, u_w, u_p, u_q)\mathbf{r} = B_{w-u} \cdot (\delta \omega_1 \delta \omega_2 \delta \omega_3 \delta \omega_4)^\mathbf{r} + B_{w-u} \cdot (\delta \omega_1 \delta \omega_2 \delta \omega_3 \delta \omega_4)^\mathbf{r}$, with $B_{w-u} = (B_1 B_2 B_3 B_4)$, $B_{w-u} = (B_1 B_2 B_3 B_4)$, and

$$B_i = \begin{pmatrix} a_{i,0} \cdot s_\psi \cdot c_\theta \\ a_{i,0} \cdot s_\theta \\ a_{i,0} \cdot c_\psi \cdot c_\theta \\ a_{i,0} \cdot c_\theta \\ b_{i,0} \cdot s_\psi \cdot c_\theta \\ b_{i,0} \cdot s_\theta \\ b_{i,0} \cdot c_\psi \cdot c_\theta \\ b_{i,0} \cdot c_\theta \end{pmatrix}, B_{i,0} = \begin{pmatrix} 0 \\ 0 \\ -J_p s_\psi c_\theta \\ -J_p s_\theta \\ -J_p c_\psi c_\theta \\ -J_p c_\theta \end{pmatrix}, B_{i,0} = \begin{pmatrix} 0 \\ 0 \\ -J_p s_\psi c_\theta \\ -J_p s_\theta \\ -J_p c_\psi c_\theta \\ -J_p c_\theta \end{pmatrix}$$

Ideally, each of the 6DOF of the quadrotor would be decoupled and controlled independently. However, with only 4 propellers, the drone is underactuated and this is not possible. Nevertheless, it is usually possible to decouple the action of the propellers on the three rotation axes and the $z$ translation axis. In this context, let us define the $4 \times 4$ mixing matrix

$$B_{z-u} = (B_{w-u})^{-1}$$

A way to decouple $u, v, q$, and $r$ is to introduce the decoupled control signals $(v_w, v_p, v_q, v_r)$ such as
\[
(u_1, u_2, u_p, u_q, u_r)^T = B_{\omega \rightarrow u} \cdot B_{v \rightarrow \omega} \cdot (v_w, v_p, v_q, v_r)^T + B_{\omega \rightarrow u} \cdot B_{v \rightarrow \omega} \cdot (v_w, v_p, v_q, v_r)^T.
\]

The three rotation axes can be fully decoupled: the propellers action on the
\[x\]
axis is given by \[\dot{\psi}_1 \theta_1 l_{x1} l_{y1} \theta_1 a_1 b_1 J_{p1}\]
\[
\psi_2 \theta_2 l_{x2} l_{y2} a_2 b_2 J_{p2} \]
\[
\psi_3 \theta_3 l_{x3} l_{y3} a_3 b_3 J_{p3} \]
\[
\psi_4 \theta_4 l_{x4} l_{y4} a_4 b_4 J_{p4}
\]
with \(l_x > 0, l_y > 0, a > 0,\) and \(b > 0.\) We then find the usual expressions
\[
B_{\omega \rightarrow u} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
-l_a & -l_a & -l_a & -l_a \\
l_{vy} - l_{vy} & l_{vy} & l_{vy} & l_{vy}
\end{pmatrix},
B_{\omega \rightarrow v} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & -b & -b
\end{pmatrix}
\]
The propellers action on the \(x\) and \(y\) translation axes are null and their action on the \(z\) translation axis and the three rotation axes can be fully decoupled: \(B_{\omega \rightarrow u} \cdot B_{v \rightarrow \omega} \cdot B_{v \rightarrow u} \cdot B_{v \rightarrow \omega} = \begin{pmatrix} 0, 1, 0, 0 \end{pmatrix} \begin{pmatrix} 0, 1, \frac{1}{s} \end{pmatrix}.\) Then, we can write
\[
u_s(s) = 0, \quad u_v(s) = 0, \quad u_w(s) = \nu_w(s),\]
\[
u_p(s) = \nu_p(s), \quad u_q(s) = \nu_q(s), \quad u_r(s) = (1 + \frac{J_r}{s}) \nu_r(s),
\]
with \(s\) the Laplace variable. To simplify the notation, the dependence on the \(s\) variable of the input/output signals is further omitted. Finally, using (6) and (9), we can write the following transfer functions
\[
u_u(s) = \frac{1}{s(C_\omega + J_\omega s)(C_\omega + m s)} \nu_q, \quad w_u = \frac{1}{s(C_\omega + m s)} \nu_w,
\]
\[
u_u(s) = \frac{1}{s(C_\omega + J_\omega s)(C_\omega + m s)} \nu_p, \quad r = \frac{1}{s(C_\omega + m s)} \nu_r
\]
Propellers inertia induces a zero in the yaw dynamics. The latter is usually significant, and allows us to reduce and to smooth the control signals on this axis during dynamic flight phases.

**V4 Quadrotor.** On an X4 configuration, the yaw axis is controlled using the propellers drag and the reaction torques. These tend to be one or more orders of magnitude inferior to the torques induced by the propellers lift on the roll and pitch axes. One way to improve a quadrotor dynamics on its yaw axis is then to tilt its propellers in a V-shape, as illustrated on Fig. 3. Sometimes only the rear propellers are tilted (called a V-Tail or Y4 configuration). In this context, we choose the same parameters as (8) with the difference \(\psi_1, \psi_2, \psi_3, \psi_4 = (\pi - \vartheta, \vartheta, \pi - \vartheta, \vartheta)\) and \((l_{x1} l_{y1} l_{x2} l_{y2}) = (l_2 l_2 l_2 l_2),\) with \(\vartheta \in [0, \pi/2].\)

Such a configuration leads to
\[
B_{\omega \rightarrow u} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
-a_a & -a_a & -a_a & -a_a \\
-a_b & -a_b & -a_b & -a_b
\end{pmatrix}
\]
\[
B_{\omega \rightarrow v} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & -b & -b \\
0 & 0 & -b & -b
\end{pmatrix}
\]
A part of the propellers lift is now added to their drag torques on the yaw axis, improving the dynamics of the drone on this axis. However, these drag torques also appear on the pitch axis now, and counter a part of the propellers lift, degrading the dynamics on this axis.

Inversing the rotation direction of each propeller (by changing the angles \(\psi_1, \psi_2, \psi_3, \psi_4 \rangle\) leads to
\[
B_{\omega \rightarrow u} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
-a_a & -a_a & -a_a & -a_a \\
-a_b & -a_b & -a_b & -a_b
\end{pmatrix}
\]
\[
B_{\omega \rightarrow v} = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & -b & -b \\
0 & 0 & -b & -b \\
0 & 0 & -b & -b
\end{pmatrix}
\]
The propellers lift now counters the propellers drag on the yaw axis, degrading the yaw dynamics. Since the propellers have been tilted in order to increase the yaw dynamics, this solution is not pertinent here. For this reason, hereafter, we will keep the directions of rotation as shown on Fig. 1 for the propellers.

Using the expressions
\[
B_{\omega \rightarrow u} = \begin{pmatrix} 0, 0, 0, 0 \end{pmatrix}, \quad B_{v \rightarrow \omega} = \begin{pmatrix} 0, 1, 0, 0 \end{pmatrix}
\]
\[
B_{\omega \rightarrow u} \cdot B_{v \rightarrow \omega} = \begin{pmatrix} 0, 0, 0, 0 \end{pmatrix}
\]
the following transfer functions are obtained
\[
u_{u} = 0, \quad u_{v} = K_p v_{p}, \quad u_{w} = v_{w},
\]
\[
u_{u} = v_{p}, \quad u_{q} = (1 + r_\vartheta s) v_{q}, \quad u_{r} = (1 + r_\vartheta s) v_{r}
\]
The differences with respect to (9) are the following: \(u_v\) and \(u_w\) are now coupled and a zero appears on the pitch axis, as a part of the torques induced by the propeller inertia. For realistic \(\vartheta\) angles and \(a, b,\) and \(l_p\) coefficients, the propellers lift action on the pitch axis is still much stronger than the action of the propellers drag torques, and \(b a < a l_p c a.\) This zero on the pitch axis is usually a positive real scalar, inducing a nonminimum phase behaviour on the pitch axis. However, this is usually a high frequency zero that only affects the very beginning of the transient response of the pitch axis (see Section 4).

Finally, using (6), we can write the next transfer functions
\[
u_u = -m g R_{\pi} s(C_\omega + J_\omega s)(C_\omega + m s) v_{p}, \quad w_u = \frac{1}{s(C_\omega + m s)} v_{w},
\]
\[
u_u = \frac{m g + K_p b_{\alpha_\vartheta} x_{\omega}}{s(C_\omega + J_\omega s)(C_\omega + m s)} v_{p}, \quad r = \frac{1}{s(C_\omega + J_\omega s)} v_{r}
\]
It can be noticed that zeros are introduced in the transfer functions of the speeds $u$ and $v$, in comparison to the X4 configuration.

**Asymmetrical Quadrotor.** Due to payloads, aerodynamic design or other reasons, industrial quadrotors can have asymmetric configurations. For instance, the distance $||\vec{G}||$ can differ from one propeller to another, or the propellers themselves can be different. We study here a drone which has a front/back asymmetry, but the same reasoning can be applied to other configurations. The difference with (8) is (superscript $f$ for front, $b$ for back)

$$
\begin{bmatrix}
I_{x1} & I_{y1} & a_{1} & b_{1} & J_{p1} \\
I_{x2} & I_{y2} & a_{2} & b_{2} & J_{p2} \\
I_{x3} & I_{y3} & a_{3} & b_{3} & J_{p3} \\
I_{x4} & I_{y4} & a_{4} & b_{4} & J_{p4}
\end{bmatrix}
= \begin{bmatrix}
I_{x1} & I_{y1} & -I_{x1} & a_{1} & -b_{1} & J_{p1} \\
I_{x2} & I_{y2} & -I_{x2} & a_{2} & -b_{2} & J_{p2} \\
I_{x3} & I_{y3} & -I_{x3} & a_{3} & -b_{3} & J_{p3} \\
I_{x4} & I_{y4} & -I_{x4} & a_{4} & -b_{4} & J_{p4}
\end{bmatrix}
$$

Such a configuration leads to

$$
\begin{align*}
B_{w\rightarrow u} & = \begin{pmatrix} 0_2 & 2 \end{pmatrix} \\
B_{w\rightarrow u} & = \begin{pmatrix} 0_2 & 2 \end{pmatrix}
\end{align*}
$$

with $\tau_{pr} = \frac{b_{p}^2 I_{p1} - b_{p} I_{p2}^2}{a_{p}^2 + b_{p}^2 I_{p1}^2 + a_{p} b_{p} I_{p2}^2}$. Depending on the configuration, propellers inertia can now couple the roll and yaw axes during dynamic flight phases, i.e.

$$
\begin{align*}
u_{w} &= v_{w}, \quad \psi_{p} = \psi_{q}, \quad \omega_{u} = \psi_{u}, \\
u_{p} &= (1 + \tau_{rr} s)v_{l} + \tau_{rr} s v_{p}
\end{align*}
$$

For the same set of parameters as in (11), with the difference $(\dot{\psi}_{1}, \dot{\psi}_{2}, \dot{\psi}_{3}, \dot{\psi}_{4}) = (\frac{\dot{\theta}_{1}}{s} - \frac{\dot{\theta}_{2}}{s} - \frac{\dot{\theta}_{3}}{s}), (\dot{\theta}_{1}, \dot{\theta}_{2}, \dot{\theta}_{3}, \dot{\theta}_{4}) = (\pi - \dot{\theta}^f \dot{\theta}^f \pi - \dot{\theta}^p \dot{\theta}^p)$, $(I_{x1} I_{y2} I_{y3} I_{y4}) = (I_{x1} I_{y1} I_{y2} - I_{y1}^2)$, i.e. a V-shaped quadrotor with front/back asymmetries, we can show that

$$
\begin{align*}
B_{w\rightarrow u} & = \begin{pmatrix} 0 & 0 & 0 & 0 & K_{pr} & 0 & 0 & 0 \\
0 & K_{pr} & 0 & 0 & K_{rr} & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{align*}
$$

with $K_{pr}, K_{rr}, \tau_{wr}, \tau_{pr}$ having a null/positive/negative value, depending on the configuration, $\tau_{wr}$ usually negative as previously seen and inducing a positive zero in the pitch dynamics, and $\tau_{pr}$ usually positive. This leads to

$$
\begin{align*}
u_{w} &= K_{pr} v_{p} + K_{rr} v_{r}, \quad \omega_{u} = \omega_{w}, \quad \psi_{p} = \psi_{q}, \\
u_{p} &= (1 + \tau_{qq} s)v_{q} + \tau_{qq} s v_{w}, \\
u_{r} &= (1 + \tau_{rr} s)v_{l} + \tau_{rr} s v_{p}
\end{align*}
$$

The transfer functions of the linearized model (6) become

$$
\begin{align*}
u_{w} &= -m_{g} \frac{1}{s} (C_{q} + J_{y}) (C_{y} + m s) \left( (1 + \tau_{qq} s)v_{q} - \tau_{wr} v_{w} \right) \\
v &= \frac{m_{g} + K_{pr} C_{p} s + K_{rr} J_{y} s^{2}}{s (C_{p} + J_{y})} v_{p} + \frac{K_{rr}}{C_{y} + m s} v_{r} \\
v_{w} &= \frac{1}{C_{y} + m s} v_{w}, \quad r = \frac{1 + \tau_{rr} s}{C_{y} + J_{y}} v_{r} + \frac{\tau_{pr} s}{C_{y} + J_{y}} v_{p}
\end{align*}
$$

The front/back asymmetry can then couple the roll and yaw dynamics, and the pitch and vertical acceleration dynamics. Up to two additional zeros can be introduced in the pitch and yaw dynamics depending on the configuration. These real zeros can be positive or negative, depending on the configuration.

![Fig. 4. Propellers speed at the hovering equilibrium state $\omega_{h}$, and steady state propellers speed control signals $\delta_{wi}$ in response to $v_{w}$, $v_{q}$, and $v_{r}$ steps, for different V angles of a given symmetric V4 quadrotor.](image)

4. SIMULATION RESULTS

**Motor model.** For the following simulation study, each brushless motor is controlled by a rotation speed controller which is assumed to confer the motors a second order low-pass filter behaviour near the hovering equilibrium state

$$
\delta_{wi} = 2 \omega_{h} \omega_{i} + \omega_{i} \omega_{i} \delta_{wi} = \omega_{i} u_{wi}
$$

We also assume that the control law is designed to give the same dynamics to each motor, regardless the asymmetry of the drone. For the following simulations, these second order filters have a damping factor $\xi$ close to 1.

**Case 1: V4 quadrotor simulation.** A simulation of the linear model was performed for a symmetric quadrotor in V4 configuration, for different values of the V-angle $\vartheta$, and with a realistic set of parameters (mass, inertia, thrust and drag coefficients, $||\vec{G}||$ distances). For a V-angle of 10° on each propeller, the required propellers rotation speeds $\delta_{wi}$ to achieve a given torque on the yaw axis was divided by two in steady state (see Fig. 4). In the mean time, those required to obtain a given torque on the pitch axis and a given force on the z axis were nearly unchanged (less than 5% higher), up to a $\vartheta$ angle of 20° ($\sim 10\%$ higher).

Fig. 5 shows the evolution of the total propellers torque on the pitch axis $u_{q}$ in response to a step of decoupled control torque $v_{q}$. The impact of the V-angle on a PID-controlled pitch angle closed-loop was also simulated. The PID controller was tuned for a 0° V-angle, and its robustness regarding the positive real zero introduced by the V-angle is presented Fig. 6. As expected, the bigger the V-angle $\vartheta$, the stronger the nonminimum phase behaviour in the pitch dynamics. However, the step response of $u_{q}$ typically reaches its minimum in less than 10ms (Fig. 5), and the overshoot increases by 20% for a 40° V-angle on Fig. 6, and could be reduced by retuning the PID controller. Hence, the nonminimum phase behavior on the pitch axis is hardly visible for an angle $\vartheta$ that could reasonably be encountered on a potential industrial quadrotor.

In the mean time, Fig. 7 illustrates that as $\vartheta$ increases, the impact of propellers inertia and, dramatically decreases on the yaw axis ($\sim$ halfed for $\vartheta = 20°$). As a consequence, if the V4 configuration improves the static gain between propellers speeds and propellers torques on $\omega_{h}$, it could degrade the bandwidth on the yaw axis.
The impact of the coupling gain $K_{pv}$ in (10) is illustrated by Fig.8. The force generated by the term $mg \varphi$ (in blue solid line) behaves more or less as a double integrator regarding $v_q$ (and does not depend on $\theta$). The dashed red line stands for the evolution of the term $K_{pv} v_p$, consisting in a simple static gain. Only the motor dynamics remains (also present in the term $mg \varphi$), giving here a second order low-pass filter behavior. The red line represents the sum of these two terms, and can be compared to the blue line to emphasize the extra dynamics added by the term $K_{pv} v_p$ on the V4 configuration.

Consequently, for a quadrotor designed to achieve high velocities around $x_B$, it could be more interesting to tilt the propellers around $y_B$, instead of $x_B$. This way, the roll dynamics would be degraded, leading to a nonminimum phase behaviour, in favour of a better yaw dynamics, while the pitch dynamics would have a slightly higher bandwidth due to a coupling term between $v_q$ and $u_q$.

In future work, a more profound study will be conducted on the nonlinear MIMO dynamics of the quadrotor, in order to better measure the impact of these coupling terms and additional zeros. Tests on a real system will be carried out in order to experimentally validate the results obtained in the simulation study.

In particular, far from the hovering equilibrium, not only the linearizations conducted Section 2 are not valid anymore, but much more complicated phenomena become significant. As described in Bristeau et al. (2009) or Huang et al. (2009), the propellers thrust can significantly deviate from their rotation axis due to aerodynamic effects. The drone body itself can also deform when experiencing high mechanical stress, modifying the orientation of the propellers.

In this context, there may be situations where, while the propellers are indeed oriented in a V-shape, their thrusts are not, or the effects of the V-shape become negligible regarding, for instance, other phenomena.
