We investigate analytically, numerically and experimentally the spectral broadening of pulses that undergo the formation of dispersive shocks, addressing in particular pulses in the range of tens of ps generated via electro-optic modulation of a continuous-wave laser. We give an analytical estimate of the maximal spectral extension and show that super-Gaussian waveforms favor the generation of flat-topped spectra. We also show that the weak residual background of the modulator produces undesired spectral ripples. Spectral measurements confirm our estimates and agree well with numerical integration of the nonlinear Schrödinger equation.

OCIS codes: (190.4370) Nonlinear optics, fibers; (190.5530) Pulse propagation and temporal solitons.

Dispersive shock waves (DSWs) or undular bores are expanding nonlinear wave packets composed of adjacent rapid oscillations slowly modulated in amplitude and frequency, which have been investigated in different physical contexts [1-4]. Coherent DSWs develop in homogeneous or disordered media exhibiting strong nonlinearity, weak dispersion and negligible dissipation. In such media the shock waves originates from a wave-breaking process or “gradient catastrophe” regularized by dispersive effects. In optical fibers such wave-breaking have been observed long ago in the normal dispersive regime when self-phase modulation (SPM) dominates [5-7]. More recently such regime has conveyed a renewed interest, considerably extending the importance of fiber DSWs [8-15]. The main signature of DSWs is the appearance of temporal undulations near the pulse edges that induce spectral sidelobes. The deleterious effect of these inherent temporal

oscillations can be avoided in practice with the use of non-breaking parabolic pulses [16, 17]. However, DSWs can be judiciously exploited to generate smooth and coherent continuum spectra in normally dispersive nonlinear fibers [9]. A particularly interesting application of DSW-induced spectral broadening is the generation of flat-topped low noise frequency combs obtained by electro-optic (e-o) intensity modulation of a continuous-wave (cw) laser. The shape of the spectral envelope of such combs plays a crucial role in applications such as direct frequency comb spectroscopy [18, 19], radio-frequency photonics [20, 21] or telecommunications [22]. But because of the limited extinction ratio of high-bandwidth e-o modulators (typically 30 dB) the pulse train is superimposed on a residual continuous background. Even a weak background strongly enhances the extension and the contrast of the temporal oscillations inherent to the dispersive shock [14, 15, 23].

In this letter, we address the study of DSW-induced spectral broadening of 50-ps pulses. We evaluate the influence of the pulse shape and assess the impact of the residual background. We show that super-Gaussian pulses are best suited to generate smooth and flat-topped spectra. We propose an analytical estimate of the maximum spectral extension of the DSW, which mainly depends on the fiber parameters and input pulse peak power, but depends only slightly on the shape and duration of the input pulses. Experimental measurements carried out for different propagation distances or different input powers quantitatively confirm the analytical estimate of the pulse spectral extension and are in excellent agreement with numerical integration of the nonlinear Schrödinger equation (NLSE).

The propagation of an envelope wave A in an optical fiber is governed by the NLSE which can be written in dimensional form as:

$$i \frac{\partial A}{\partial z} - \frac{1}{2} \beta_2 \frac{\partial^2 A}{\partial t^2} + \gamma |A|^2 A + i \frac{\alpha}{2} A = 0 \quad (1)$$

where γ is the nonlinear coefficient, β_2 is the second-order chromatic dispersion coefficient and α is the linear loss. z is the propagation distance and t a local time in a frame of reference which moves at the group velocity. In the NLSE $|A|^2 = P$ is the wave power. We focus our attention here on the case of pulses generated from a cw laser, intensity modulated by an electro-optic modulator (EOM). Because any real EOM has a finite extinction ratio (ER) the pulse train always contains a cw background or leakage. The factor ER can be defined as $ER = (P+P_o)/P_o$ where P and P_o are the pulse peak-power and cw background power of the modulated light, respectively. The light modulated by a non-ideal EOM can be seen as the sum of a pulse without cw component and a leakage light. Following the procedure described in refs. [24-25] taking into account the finite ER of the intensity modulator and neglecting loss, Eq. (1) possesses the following conservation law

$$\frac{d}{dz} \left(\gamma \frac{\int (|A(z,t)|^2 - P_o)^2 dt}{2 \int (|A(z,t)|^2 - P_o) dt} + \beta_2 \frac{\int \omega^2 (|\tilde{A}(z,\omega)|^2 - P_o \delta(\omega)) d\omega}{2 \int (|\tilde{A}(z,\omega)|^2 - P_o \delta(\omega)) d\omega} \right) = 0. \quad (2)$$

The two terms of Eq. (2) have a dimension of an inverse length, and can be considered as a generalization of the inverse of the standard nonlinear and dispersion lengths [24]. In practice, for a pulse propagating in the highly nonlinear regime, only the first integral will be relevant; conversely in the purely dispersive regime only the second integral matters. Equation (2) can be rewritten as [24]:

$$\mathcal{L}_{NL}^{-1}(z) + \mathcal{L}_D^{-1}(z) = C, \quad (3)$$

where C is a constant fixed by the input conditions.

Here, in the general case the input conditions correspond to an e-o wave consisting of 50-ps pulses of peak power P and normalized power profile $f(t)$ superimposed on a residual continuous background of power P_o . The e-o wave propagates through a highly dispersive single mode fiber with $\beta_2 = 0.119 \text{ ps}^2 \text{ m}^{-1}$ and $\gamma = 4.6 \times 10^{-3} \text{ W}^{-1} \text{ m}^{-1}$ at a carrier wavelength of 1560 nm.

Fig. 1. (a) Temporal and (c) spectral color map evolution vs propagation distance for a 50-ps hyperbolic secant pulse with $P = 100 \text{ W}$ and without background ($P_o = 0$). The dashed line shows the maximum spectral extension predicted by Eq. (8). (b) Evolution of $\mathcal{L}_{NL}^{-1}$ and $\mathcal{L}_D^{-1}$ versus propagation distance.

Figure 1 shows the temporal (a) and spectral (c) evolutions along the propagation distance in the particular case of hyperbolic secant pulses without background or loss. With such conditions, one can distinguish two stages of the pulse evolution. As can be seen from Fig. 1, at the early stage of propagation, the nonlinear effect, i.e. self-phase modulation, dominates, thus leading to a significant spectral broadening ($\frac{\mathcal{L}_{NL}^{-1}(z=0)}{\mathcal{L}_D^{-1}(z=0)} \cong 6200$ corresponding to an equivalent soliton number $N=52$ [9]). Subsequently, for larger propagation distances, this resulting spectral expansion, associated with a strong steepening of the pulse edges, makes dispersion to acquire weight. At the shock distance $z_c = 274 \text{ m}$ (see Fig. 1(b)), nonlinearity and dispersion have approximately the same importance ($\mathcal{L}_{NL}^{-1} = \mathcal{L}_D^{-1}$) and sidelobes appear in the spectrum. After the shock point, the pulse disperses and its peak power decreases, making the evolution progressively almost linear. In this second regime dispersion dominates and the spectrum is almost conserved while the pulse strongly temporally broadens. This process can be summarized by help of Eq. (3) as follows [24]:

$$\mathcal{L}_{NL}^{-1}(0) \approx \mathcal{L}_D^{-1}(z \gg z_c), \quad (4)$$

where $z \gg z_c$ means at a distance well beyond the shock point. In Eq. (2) we can recognize the variance of the power spectrum σ_ω^2 deprived of the cw component defined as

$$\sigma_\omega^2 = \frac{\int \omega^2 |\tilde{A}(z,\omega)|^2 d\omega}{\int |\tilde{A}(z,\omega)|^2 d\omega - P_o}. \quad (5)$$

From Eqs. (2), (4) and (5) and with an input condition $|A(0,t)|^2 = P_o + P f(t)$ the root mean square (rms) σ_ω at a propagation distance well beyond the wave-breaking point can be expressed as

$$\sigma_\omega = \sqrt{\frac{\gamma P}{\beta_2}} F, \quad (6)$$

where the dimensionless factor F is defined as

$$F^2 = \frac{\int f(t)^2 dt}{\int f(t) dt}. \quad (7)$$

The parameter F does not depend on the background level and on the input pulse duration and can be calculated explicitly for different input temporal profiles. The factor F is approximately equal to one for relevant pulses. For example $F = 2^{-1/4m}$ for a super-Gaussian of order m (e.g. $F = 0.944$ for $m = 3$). Consequently, considering that most of the spectrum ranges in the interval $[-2\sigma_\omega; 2\sigma_\omega]$, then the maximum of spectral extension $\omega_{\max}$ can be calculated as

$$\omega_{\max} \sqrt{\frac{\beta_2}{\gamma P}} = 2\sigma_\omega \sqrt{\frac{\beta_2}{\gamma P}} = 2F \cong 2. \quad (8)$$

Equation (8) shows that spectral extension depends only slightly on the pulse profile but is independent of the pulse duration and scales as $\sqrt{\gamma P / \beta_2}$ corresponding to the inverse of the average temporal period of the DSWs obtained from Whitham modulation theory [1,11,15]. This scaling is identical to that predicted for parabolic nonlinear-dispersive similaritons of passive fibers [26]. Note that for a constant pulse peak power P the maximum spectral extension does not depend on the power level P_o of the continuous background.

Fig. 2. (a) Variation of spectral broadening at the fiber output vs input temporal profile for 50 ps pulses with the same peak power P ; (b) Spectral broadening obtained for third-order super-Gaussian of different pulse durations. Here the input pulse power is $P = 100$ W and the background is zero ($P_o = 0$). The dashed lines show the maximum spectral extension predicted by Eq. (8).

These remarkable properties have been verified by numerical integration of the NLSE (1) without losses as shown in Fig. 2. Figure 2(a) shows the simulated spectral profiles obtained at the fiber output for three different input profiles of identical duration and pulse peak power P . We can see that the same spectral extension is obtained for the three profiles but that super-Gaussian pulses lead to the flattest spectrum. Figure 2(b) confirms, in the case of super-Gaussian pulses, that the spectral extension depends very little on the pulse duration over a large time scale from 20 ps to 80 ps. A good agreement is obtained with the maximum spectral extension predicted by Eq. (8) (dashed vertical lines). This latter remarkable property is also verified for other input pulse profiles and for initially chirped pulses. Note that the factor 2 in Eq. (8) is in good agreement with the fact that, well beyond the shock, the pulse spectrum becomes nearly parabolic [27] with a maximum extension equal to its rms width multiplied by $\sqrt{5} \approx 2.2$. More precisely an input parabolic pulse, for which $F = 2/\sqrt{5}$, leads to a parabolic output spectrum with a maximum extension defined by $\omega_{\max} \sqrt{\frac{\beta_2}{\gamma P}} = \frac{2\sqrt{5}}{\sqrt{5}} = 2$. Another

interesting feature is that a small continuous component due to the non-ideal EOM is sufficient to induce strong distortions of the temporal [11] and spectral profiles as visible in Figs. 3(c)-(f). Thus, in the absence of background [Figs. 3(a),(b)] both pulse and spectrum exhibit a smooth shape, while, in the presence of the latter, rapid oscillations with high contrast appear on the pulse profile as well as on the spectrum [Figs. 3(c)-(f)]. The contrast of the oscillations increases strongly with the level of the continuous background. Figure 3(f) shows that a modulator with $ER = 20$ dB generates a spectrum which is not very suitable for applications, given the strong fluctuations of its intensity. Electro-optic modulators with ER of at least 30 dB are thus required for accurate applications [18-22]. The flatness of the spectra could be easily increased by cascading two modulators. Figure 3(a) clearly shows that the pulse acquires a parabolic profile far away the shock point as already mentioned in Ref. [27].

Fig. 3. Temporal and spectral profiles obtained at the fiber output from numerical integration of the NLSE (1). The input third-order super-Gaussian pulse has a peak power $P = 50$ W: (a), (b) infinite ER (no background), (c), (d) $ER = 30$ dB, (e), (f) $ER = 20$ dB. The dashed lines show the maximum spectral extension predicted by Eq. (8).

We performed a series of experiments to illustrate the spectral broadening of the e-o pulses by the DSW process. The dispersion and nonlinear parameters of the fiber are the same as those used in the simulations and the linear loss coefficient is $\alpha = 0.55$ dB/km. A cw centered around 1560 nm is first generated by a diode laser and then intensity modulated by an EOM set at a repetition frequency of 100 MHz and delivering 52-ps third-order super-Gaussian pulses [18]. Figure 4 shows the input spectrum (black curve) together with spectra recorded for different fiber lengths from 50 m to 1400 m. Here the pulse peak power is $P = 47$ W and $ER = 30$ dB. The input optical spectrum shows a sinc squared shape as expected for nearly-square pulses. The narrow peak at the center of the spectra is the signature of the residual cw component. At propagation distance of 50 m the spectrum expands substantially and keeps broadening significantly up to a distance of 800 m. For further propagation distances the spectral range begins to saturate and the spectrum becomes more and more flat. Spectral oscillations appear due to the continuous background in good agreement with the numerical simulations of Fig. 3(d).

Fig. 4. Experimental spectra recorded at 1559.34 nm for several propagation distances ranging from 0 m (input) to 1400 m. The pulse peak power is $P = 47$ W and the extinction ratio is $ER = 30$ dB. The curves are shifted by 5 dB with respect to each other for clearness.

The spectral asymmetry originates from the slight asymmetry of the input condition (see the input spectrum with black line).

Figure 5(a) shows the variation versus propagation distance of the full width determined at -20 dB of the maximum intensity (cw component excluded) of the spectra displayed in Fig. 4. We observe that the spectral width tends rapidly towards a maximum limit value corresponding to the propagation regime dominated by dispersion. But it should be noted that the widths at -20 dB are indeed slightly less than the theoretical estimate given by Eq. (8). Let us note also an excellent agreement between the measurements and the spectral width determined from numerical integration of the NLSE (1) without any adjusted parameter and including losses. Figure 5(b) shows the spectral width measured as a function of the square root of input power at a propagation distance of 1400 m. The perfect linear evolution clearly demonstrates that the spectral extension scales as $\sqrt{P}$.

Fig. 5. (a) Variation of the full spectral width at -20 dB vs propagation distance and at a fixed pulse power $P = 47$ W. Same fiber parameters and pulse profile as in Fig. 4. (b) Spectral width evolution vs input pulse power at a propagation distance of 1400 m. Same fiber parameters and pulse profile as in Fig. 4 and ER = 30 dB.

In conclusion, we revealed the influence of the residual continuous background inherent to the finite ER of any non-ideal e-o intensity modulator. We showed that a low extinction ratio results in a substantial enhancement of the contrast of the spectral oscillations inherent to DSW and is thus unacceptable for the generation of flat and smooth spectra. Well beyond the shock distance the pulses enter into a regime dominated by dispersion and the spectrum evolution becomes quasi-stationary. We analytically calculated the maximum spectral extension and showed that, at a constant pulse peak power, it does not depend on the background level and is quasi-independent of the shape of the pulses as well as of their duration. However, we demonstrated that super-Gaussian pulses are more adapted to produce flat-topped and smooth spectra than Gaussian or hyperbolic secant pulses. The experimental measurements of the spectral width as a function of propagation distance are in good agreement with the numerical integration of the NLSE and the maximum spectral extension scales as $\sqrt{P}$. We believe that our results will be very useful for the design of e-o frequency combs dedicated to various applications and relevant to many

systems requiring spectral broadening of pulses of duration of tens of ps.
