Abstract

Surface functionalization has numerous applications worldwide. Silicon oxide has been a research material of choice. However, tin dioxide (SnO₂) films are employed in many applications especially in gas sensors, and little studied in regards of functionalization. Thus, they were chosen to be functionalized via 3-aminopropyltriethoxysilane (APTES). Different synthesis parameters were tested such as APTES grafting by vapor or liquid phases deposition. In liquid, many parameters were investigated: water presence, reaction times and APTES concentration. The presence and reactivity of grafted amine terminated film on SnO₂ were carried out by Alexa Fluor® molecules. In addition, APTES grafting was characterized using Attenuated Total Reflectance-Fourier Transform Infrared spectroscopy (ATR-FTIR) and X-ray photoelectron spectrometry (XPS) techniques. These characterizations showed how synthesis parameters affect the amount and thickness of APTES films. Optimal liquid silanization parameters were determined in order to obtain a saturated SnO₂ surface with APTES molecules. Importantly, the addition of 5 vol% H₂O to the APTES solution provided denser surface coverage, by hydrolyzing the ethoxy groups to silanol. An almost 50% improvement over anhydrous liquid and vapor methods was obtained.

Keywords: SnO₂; Functionalization; APTES; XPS; ATR-FTIR

1. Introduction

Surface functionalization is being used in wide range of applications, like surface and self-assembling monolayers (SAMs) in bio-sensors [1, 2], gas sensors [3–5], corrosion resistance of metal [6] and electronics [7]. Generally, surfaces are organically modified to enhance detection performance, surface rigidity, selectivity and sensitivity of sensors, etc. [6, 8–10]. Silanization or covering of a metal oxide surface self-assembly with organofunctional alkoxy silane molecules, using organosilanes (RSiX_3 where R is an alkyl or any other functional group and X is a leaving group) is the most commonly used method to prepare active organic monolayers on oxide films [11]. 3-aminopropyltriethoxysilane (APTES) is one of the most commonly used organosilane products to prepare an active amine terminated film on metal oxides [8]. The main advantage of an aminosilane monolayer on the surface of metal oxide is the rapid formation of covalent bonds between the oxide surface and the anchoring groups, thus stabilizing the monolayer and facilitating further modifications [12]. Furthermore, APTES has bulky alkoxy groups that improve the stability of the resulting monolayer as shown by Feng Zhang et al. [13]. The APTES films can be generally deposited on silicon and tin dioxide substrates. These films are used to attach a variety of materials such as DNA, proteins and polymers [2, 6, 14]. Moreover, the APTES molecule can also be used as intermediate step for advanced modification/functionalization in gas sensors [4, 5, 15]. To the best of our knowledge, the properties of these films such as thickness, orientation and density of the monolayer have essentially been investigated on silicon oxide [16–19]. However, only a few studies on the preparation of the APTES layer deposited on tin dioxide surface have been explored [1], even though these reactive films are also being used as gas and bio-sensors. Indeed, tin dioxide (SnO_2) is being used in many fields like gas sensors, biosensors, and electronics [2, 20, 21]. SnO_2 is often chosen for gas sensors due to its unique physical and chemical properties such as a large energy gap (3.6 eV), dielectric constant, better accuracy or repeatability at the present stage of development, environmental-friendliness and easy to synthesize. As in SiO_2 , functionalizing SnO_2 by organic molecules is of special interest to improve sensitivity, selectivity, and electrical properties in gas sensor applications and others.

In this work, we propose to study the modification of SnO_2 thick films by APTES since it is not well described in the literature. The aim was to prepare active and stable amine terminated

organic film on SnO₂ thick film prepared by a screen printing technique. Functionalization of SnO₂ film by APTES in vapor and liquid phase was investigated. Furthermore, varying silanization parameters in the liquid route like the influence of condensation reaction time, APTES concentration, and the effects of water during the reaction were examined. Finally, concentration and thermal stability of APTES on SnO₂ were also evaluated.

2. Experimental

2.1. Preparation of SnO₂ film and silanization procedures

2.1.1. Preparation of SnO₂ film

Thick SnO₂ films were deposited on alumina substrate by screen-printing technology. A semi-automatic Aurel C890 machine was used. Procedure to prepare the SnO₂ ink and film fabrication parameters was described elsewhere [22]. First, the SnO₂ powder (Prolabo Company) was mixed with a solvent and an organic binder. Second, a 40 microns oxide film (approximately) was deposited on an alpha-alumina substrate (8×8×0.4 mm³). Finally, the SnO₂ material was annealed for 10 h at 700 °C in air. The SnO₂ particles and agglomerates sizes were found to be between 10 nm and 500 nm.

2.1.2. Vapor phase silanization

The silanization of SnO₂ film by 3-aminopropyltriethoxysilane (Acros-Organics) in vapor phase has been described elsewhere [16]. First, the SnO₂ films were immersed for 5 min in acetone, ethanol and distilled water (DW) successively, and then dried with argon to remove contaminants. Second, films were treated by air/oxygen plasma (air/O₂ pressure =0.4 torr) for 4 min to create hydroxyl groups on the sample surface. Third, the SnO₂ sample and APTES (liquid) were placed side by side in closed Teflon holder. Then, the liquid was baked out at 80 °C for 1 h. The installation of SnO₂ samples and 150 µL of APTES was conducted in a dry atmosphere to avoid the humidity in cell. After 1 h silanization, the samples were rinsed with absolute ethanol. Finally, the films were annealed at 110 °C for 1 h to eliminate water trapped in the films as well as the physisorbed APTES molecules. A scheme of APTES vapor phase deposition on SnO₂ is presented in the Fig. 1.

Fig. 1. Schematic representation of the silanization process.

2.1.3. Liquid phase silanization

The liquid phase grafting of APTES considered the influence of three main parameters: anhydrous and hydrous APTES solution, APTES concentration, and reaction time. All the solutions were prepared in absolute ethanol (anhydrous ethanol). The silanization was performed by immersing the SnO₂ films in the APTES solution, with or without water, with three different APTES concentrations (1, 50 or 500 mM) at room temperature and for various durations: 5 min, 30 min, 4 h, and 5 h. To investigate whether water would hydrolyze the ethoxy groups, the 50 mM APTES solution was diluted with 5 vol% H₂O (hydrous APTES solution; i.e. solvent: 95% by volume of absolute ethanol and 5% of H₂O) for 5 min, 30 min, 4 h and 5 h immersion times. For varying hydrous APTES concentrations (1, 50 or 500 mM), SnO₂ was immersed for 5 h. After silanization, the films were rinsed with absolute ethanol, dried with N₂ and annealed at 110 °C for 1 h. The reaction carried out in absolute ethanol, 50 mM APTES solution for 5h will be called anhydrous liquid silanization.

2.2. Characterization techniques

SnO₂-APTES film can be used as intermediate step for further surface modifications. The reactivity of APTES film with respect to coupling reactions was determined by using Alexa Fluor® 488 carboxylic acid, succinimidyl ester molecule ($\lambda_{excitation} = 488\text{ nm}$). Alexa Fluor product was purchased from Life Technologies. This product reacts specifically with the primary amines that lead eventually to immobilization of fluorescent molecules on SnO₂ film. To study the feasibility of employing fluorescent molecules on APTES films, two SnO₂ samples, one with APTES (SnO₂-APTES) and the other without APTES, were immersed for one hour in a mixture

of 4 μL of Alexa Fluor and 3 mL of solution of sodium carbonate and sodium bicarbonate, pH 9, at room temperature. Afterwards, the samples were rinsed with absolute ethanol. Alexa Fluor molecules were detected by epifluorescence measurements using an BX41M optical microscope (Olympus, Tokyo, Japan), fitted with a 100 W mercury lamp, a cyanide Cy3 dichroic cube filter (excitation 550 nm, emission 580 nm) and a cooled Spot RT monochrome camera (Diagnostic, Sterling Heights, MI, USA). The intensity of film fluorescence was measured by Tecan Infinite M1000 in order to determine qualitatively the APTES on the surface of SnO_2 film. The fluorescence intensity measurements were carried out at 494 nm as excitation wavelength and 517 nm emission wavelength with an integration time of 20 μs and a settle time of 10 ms.

The influence of silanization parameters (vapor or liquid synthesis, and in liquid process: water content, APTES concentration, reaction time) were evaluated via Attenuated Total Reflectance-Fourier Transform Infra-Red spectroscopy (ATR-FTIR). Samples were placed face-down on the diamond crystal, and a force was manually applied by pressure tip. FTIR spectra were recorded in wavelengths ranging from 400 to 4000 cm^{-1} with a resolution of 2 cm^{-1} . The entire ATR-FTIR spectra were collected using a Golden Gate Diamond ATR accessory (Bruker Vertex 70).

In order to check the presence, concentration, and the thermal stability of APTES films on SnO_2 , chemical surface analysis were carried out using X-ray Photoelectron Spectroscopy XPS. The analysis were performed with a Thermo VG Thetaprobe instrument with a focused monochromatic Al $K\alpha$ source ($h\nu=1486.6$ eV, 400 μm spot size). Photoelectrons were analyzed using a concentric hemispherical analyzer operating in the constant ΔE mode. The energy scale was calibrated with sputter-cleaned pure reference samples of Au, Ag and Cu in order that the Au 4f_{7/2}, Ag 3d_{5/2} and Cu 2p_{3/2} were positioned at a binding energies of respectively 84, 386.2 and 932.7 eV. Spectra were recorded in the binding energy range of 0–1200 eV with step size of 1 eV and pass energy of 300 eV for survey scans, step size of 0.1 eV and pass energy of 50 eV for narrow C 1s, O 1s, N 1s, Si 2p, Sn 4d and Sn 3d scans. The two pass energies give energy resolution (width of the Ag 3d_{5/2} peak) measured on sputter clean silver samples of respectively 1 eV and 0.5 eV. During XPS experiments, charge compensation was achieved by irradiation of the sample with a system combining a diffuse beam of low energy electrons and low energy ions. Optimum charge compensation was performed in order to have the narrower-shape of the tail at

the low binding energy of Sn 3d peak. Analysis of the different components of C 1s, O 1s, N 1s and Si 2p photoelectron peaks were carried out using synthetic line shapes consisting of a convolution product of a Gaussian function with 30% of a lorentzian function. To study APTES thermal stability, SnO₂-APTES films were in-situ annealing at 200 °C, 300 °C, 400 °C and 500 °C, for 4 h in a preparation chamber connected to the spectrometer at a pressure of 5.10⁻⁹ mbar .

3. Results and Discussions

3.1. Influence of silanization process and synthesis parameters.

Figure 2 shows the epifluorescence microscope images of SnO₂ (Fig. 2a) and SnO₂-APTES after silanization in vapor (Fig. 2b) and liquid phase (synthesis parameters: 50 mM of hydrous APTES solution, immersed for 5 h, Fig. 2c) modified by Alexa Fluor. For SnO₂ (Fig. 2a), no fluorescence is observed. On the contrary, the obtained fluorescence of SnO₂-APTES films (Fig. 2b and 2c) means that the Alexa Fluor molecules were attached to the surface by the grafted amine terminal film of APTES. The fluorescence intensity of APTES modified SnO₂ in vapor phase was 3185 in arbitrary units while it was 4541 by liquid silanization. The fluorescence intensities show that more reactive amine groups are present on the surface for the SnO₂-APTES carried out in liquid phase.

Fig. 2. Epifluorescence images after immersion in Alexa Fluor solution: a) SnO₂, b) SnO₂-APTES-vapor phase and c) SnO₂-APTES-liquid phase (5 vol% H₂O, 50 mM of APTES, 5 h).

In order to compare the synthesis parameters, Attenuated Total Reflectance-Fourier Transform Infra-Red spectroscopy (ATR-FTIR) was used. The most important signals corresponding to APTES were found between 800 and 1800 cm⁻¹ as shown in Fig. 3. The peak at 938 cm⁻¹ is

attributed to Sn-O-Si stretch [4]. The strong mode at 1029 cm^{-1} is attributed to siloxane group (Si-O-Si) from polymerized APTES, this mode being proportional to the thickness of the APTES layer [23]. The peak at 1070 cm^{-1} arises from the un-hydrolyzed ethoxy groups of APTES ($-\text{OCH}_2\text{CH}_3$) [24]. The strong absorption peak at 1125 cm^{-1} is attributed to Si-O bond of either polymerized or physisorbed APTES [17]. The vibrational mode around 1390 cm^{-1} is assigned to Si-C bond ($-\text{Si}-\text{CH}_2-$) [17]. NH_2 vibrational signal is found at 1570 cm^{-1} and confirms the presence of amine end functional group of APTES after silanization. The two peaks present at 1496 and 1643 cm^{-1} correspond respectively to the symmetric and asymmetric $-\text{NH}_3^+$ group indicating the protonation of amine group in air [25, 26].

Different parameters were explored for APTES grafting: vapor and liquid silanization with or without H_2O (Fig. 3a), APTES concentrations (Fig. 3b) and reaction times (Fig. 3c). As shown in Fig. 3 a), APTES liquid synthesis with 5 vol% H_2O (red curve) shows more intense vibrational modes which imply that more APTES molecules were grafted on the surface in this synthesis. Furthermore, the observed peak at 1070 cm^{-1} in the case of vapor silanization (green curve) and liquid synthesis without H_2O (blue curve) is linked to un-hydrolyzed ethoxy groups of APTES as mentioned earlier. This peak has disappeared for the SnO_2 -APTES film done with H_2O . The water molecules initiate the silanization process by hydrolysis of ethoxy groups to create corresponding hydroxysilane ($\text{RSi}(\text{OH})_3$) [12]. Hydrolysis of ethoxy groups of APTES pushes forward the condensation reaction with SnO_2 film and with APTES to each other [26, 27]. From these results, one can notice that the presence of water in the synthesis solution increases the APTES grafting on SnO_2 with also more APTES molecules bonding.

Fig. 3. ATR-FTIR spectra of SnO₂ and SnO₂-APTES with different silanization parameters: a) vapor phase and liquid phase in ethanol with and without H₂O, 50 mM APTES, 5 h, b) hydrous liquid phase in ethanol (5 h); APTES concentrations of 1, 50 and 500 mM, c) hydrous liquid phase in ethanol (50 mM APTES); immersion times of 5 min, 30 min, 4 h and 5 h.

In Fig. 3 b), 3 APTES concentrations were tested in ethanol solution with 5 vol% H₂O for 5 h. Peaks intensities of Si-O bonds at 1029 and 1125 cm⁻¹ are low with 1 mM APTES solution (green curve) while they increase with 50 mM (red curve) and then almost no change is noticed when the concentration is increased up to 500 mM (purple curve). That means that a very little amount of APTES was grafted on the surface with a concentration of 1 mM while a concentration of 50 mM was sufficient for appropriate APTES functionalization.

Figure 3 c) shows different reaction times of SnO₂ film in APTES solution (ethanol with 5 vol% H₂O, 50 mM of APTES). The peak of Si-O-Si (1029 cm⁻¹) rises with the increase of reaction time. As this peak is proportional to the amount of APTES attached on the surface [23], one can note that the increase of reaction time from 5 min to 4 h attaches a larger amount to the surface. No surge in the amount of grafted APTES on the surface was observed after 4 h, since the signal intensity is the same between films immersed 4 and 5 h. Evidently, this steady state means that 4 h is sufficient to saturate the SnO₂ film with APTES.

3.2. Surface concentration of APTES on SnO₂

3.2.1. Film as synthesized

The XPS survey scan spectrum of SnO₂-APTES film obtained by liquid phase synthesis, presented in Fig. 4 shows the presence of Sn and O related to the SnO₂ substrate and as well as N, C and Si related to APTES molecules at the surface which confirms the silanization of SnO₂. Similar surveys spectrum were found for the others APTES film synthesis methods.

Fig. 4. XPS survey spectrum of SnO₂-APTES synthesized in hydrous liquid phase.

Peak fitting of C 1s, O 1s, N 1s and Si 2p narrow scans allowed to determine different chemical bonds which were in agreement with the presence of APTES molecules as shown in Fig. 5. Three components at 284.2 eV, 284.9 eV and 289.5 eV were found for C 1s peak (Fig. 5a) which were

assigned respectively to C-Si, C-C/CH and C-N chemical bonds. The nitrogen N 1s core level (Fig. 5b) exhibits two contributions, one located at 399.4 eV which is related to amine group bounded to carbon C-NH₂. The second located at 401.3 eV, could be attributed to C-NH₃⁺ [28]. The shape of the O 1s peak (Fig. 5c) was adjusted using two components at 530.3 eV, and 531.8 eV according to oxygen in Sn-O, and Si-O respectively [2]. Finally, the Si 2p peak located at 101.9 eV (Fig. 5d) was assigned to Si atom bounded to oxygen and carbon in the APTES molecule. Comparing with the two others experimental procedures for silanization of SnO₂, the only difference was observed on the shape at the low binding energy of the O 1s peak for the hydrous liquid silanization procedure which was attributed to the presence of residual H₂O.

Fig. 5. XPS peak fitting of a) C 1s, b) N 1s, c) O 1s, and d) Si 2p of SnO₂-APTES film.

3.2.2. Nanostructure of the APTES film on SnO₂

Nanostructure of the APTES film was determined from inelastic electron background analysis of the Sn 3p transition taking advantage of the weak sensitivity of this method to the roughness. “Analyze” program from QUASES software package developed by Tougaard [29] was used by means of the active substrate model where the modelled signal originates from the SnO₂ substrate and is attenuated by an overlayer constituted of APTES molecules. The shape of the measured spectrum $J(E)$ strongly depends on the morphology of the overlayer. A primary excitation spectrum $F(E)$ is obtained after correction of the measured spectrum $J(E)$ by an inelastic background calculated for a given coverage and thickness of the overlayer. These set of parameters can be adjusted using two criterions. The first one is that after background subtraction $F(E)$ must be of zero intensity in an energy region beyond 30 eV below the primary peak energy. As a second criterion, $F(E)$ can be compared to the one determined from the analysis of spectrum on reference sample with well-known in depth concentration profile. Reference Sn 3p spectrum was recorded on a pure SnO₂ sample. After linear background subtraction and analyzer transmission function correction, the background of the model spectrum was adjusted to zero by analyzing the reference to the depth of 1000 Å that corresponds to the infinite thick homogeneous layer. The background was calculated using ‘Universal cross section’ formula [30] for the inelastic electron cross section and changing the “x-scale” parameter in the QUASES program from default value to 0.97. A value of 12.36 Å for the inelastic mean free path of Sn 3p electrons in SnO₂ was considered according to the TPP2M method [31]. The same procedure and parameters were used for analyzing SnO₂ covered with APTES molecules using “active substrate” model.

Results obtained after analysis of Sn 3p spectrum measured on SnO₂ samples with different methods of silanization are presented in the Fig. 6. From these results, two main conclusions can be drawn. Firstly, for the three methods of silanization (vapor, hydrous liquid, anhydrous liquid), the nanostructure of the grafted film consist of a monolayer of APTES molecules which does not cover entirely the surface. Secondly, the silanization procedures used can be classified as “high coverage” for the hydrous liquid method (SnO₂ surface coverage of 0.8) and “low coverage” for the two other methods where a similar SnO₂ surface coverage around 0.5 was found.

Finally, it is worth noting that considering a theoretical length of the APTES molecule of 8 Å, the calculated overlayer thickness of 6 Å indicate a $\sim 42^\circ$ grafting angle of the APTES molecules with respect to the normal of the SnO_2 surface.

Fig. 6. a) Modelisation of the electron inelastic background of Sn 3p using QUASES software [29], b) c) and d) schematic representations of the coverage and thickness of the APTES overlayer for the three methods used for the silanization of SnO_2 .

3.2.3. Determination the concentration of APTES on SnO_2

As shown before using electron inelastic background analysis, the silanization of SnO_2 with vapor, hydrous liquid and anhydrous liquid methods produce a monolayer film of APTES molecules which does not cover entirely the SnO_2 . Owing to the difference in coverage rate according to the experimental silanization protocol, it seems interesting to determine the concentration of APTES molecules grafted on SnO_2 for each method. Considering one silicon atom for each APTES molecule, these concentrations were estimated calculating the silicon

concentration per unit area using the ratio of the intensities of Si 2p and Sn 4d photoelectron peaks. The choice of these peaks, especially Sn 4d which is much less intense than Sn 3d, was motivated by the fact that several assumptions can be made due to the position at high kinetic energies of these transitions as we will see below. For the purpose of this calculation, we define three thicknesses: $d_{C_3NH_8}$, d_{Si} and d_{APTES} . These parameters are presented in the Fig. 7 and correspond to different portions of the APTES film.

Fig. 7. Schematic illustration of the different portions of the APTES film considered for the calculation of the APTES surface concentration using the ratio of Si 2p and Sn 4d intensities.

Using the description in Fig. 7, the intensities of Si 2p and Sn 4d can be described as shown in equations 1 and 2.

$$\text{Eq. (1)} \quad I_{Si2p} = KT_{Si2p} \sigma_{Si2p} N_{Si} \lambda_{Si2p}^{Si} \cos \theta \left[1 - \exp \left(\frac{-d_{Si}}{\lambda_{Si2p}^{Si} \cos \theta} \right) \right] \times k_{Si2p}^{C_3NH_8}$$

$$\text{Eq. (2)} \quad I_{Sn4d} = KT_{Sn4d} \sigma_{Sn4d} N_{Sn} \lambda_{Sn4d}^{SnO_2} \cos \theta \times k_{Sn4d}^{APTES}$$

with

K depending on instrumental factors and analysis conditions (K is the same for all elements during the analysis of a given specimen),

T_A the transmission function of the spectrometer at a kinetic energy corresponding to the photoelectron peak A,

σ_A the photoionization cross section of the core level A,

N_x the atomic concentration per unit volume of the element x,

θ the escape angle of photoelectrons with respect to the normal of the surface of the analyzed specimen,

$k_A^M = \exp\left(\frac{-d_M}{\lambda_A^M \cos \theta}\right)$ the attenuation factor of an electron of A in the matrix M and

λ_A^M the inelastic mean free path for an electron A in the matrix M.

Concerning the inelastic mean free path two methods were applied. The values of λ_{Si2p}^{Si} and $\lambda_{Sn4d}^{SnO_2}$ were estimated using the TPP2M method [31] which give respectively 30.8 Å and 24.1 Å. As regards the value of λ_{Si2p}^{Si} , one may assume that $d_{Si} \ll \lambda_{Si2p}^{Si}$ which allows to modified the equation 1 and express the intensity of Si2p as a function of the silicon atomic concentration per unit area in equation 3.

$$\text{Eq. (3)} \quad I_{Si2p} = KT_{Si2p} \sigma_{Si2p} n_{si} \times k_{Si2p}^{C_3NH_8}$$

With $n_{Si} = N_{Si} d_{Si}$

The silicon surface concentration can be consequently expressed in function of the ratio of the intensities of Si 2p and Sn 4d following the equation 4.

$$\text{Eq. (4)} \quad n_{si} = \frac{I_{Si2p}}{I_{Sn4d}} \times \frac{T_{Sn4d} \sigma_{Sn4d} N_{Sn} \lambda_{Sn4d}^{SnO_2} \cos \theta}{T_{Si2p} \sigma_{Si2p}} \times \frac{k_{Sn4d}^{APTES}}{k_{Si2p}^{C_3NH_8}}$$

For $\lambda_{Si2p}^{C_3NH_8}$ and λ_{Sn4d}^{APTES} , a method using quantitative structure-property relationships in organic materials [32] was used. Inelastic mean free paths were determined using the following expression:

$$\text{Eq. (5)} \quad \lambda(nm) = \left[\frac{3.117 \left({}^0\chi^V \right) + 0.4207 N_{rings}}{N_{non-H}} \right] (E / keV)^{0.79}$$

With

N_{rings} the number of aromatic six-member rings in the molecule,

N_{non-H} the number of atoms in the molecule excluding hydrogen,

E the kinetic energy of the electron travelling through the molecule and

$${}^0\chi^v = \sum_{\text{non-H atoms}} \left(\frac{1}{\sqrt{\delta^{(v)}}} \right) \text{ the zeroth-order valence connectivity index of the molecule and}$$

$\delta^{(v)}$ the valence connectivity index which depends on the hybridization state and number of hydrogen atoms bonded to the atom considered. Values of $\delta^{(v)}$ were taken from literature using Bicerano work [33].

The values of inelastic mean free path and associated attenuation factors, assuming a collecting angle θ of 50°, are presented in the Table 1.

Table 1. Values of inelastic mean free path λ and associated attenuation factor k calculated using the Cumpson method [32] for an electron with kinetic energy E travelling through a given matrix with thickness d .

Matrix	Peak, E Kinetic (eV)	$d^{\text{Matrix}}(\text{\AA})$	$\lambda_{\text{peak}}^{\text{Matrix}} (\text{nm})$	$k_{\text{peak}}^{\text{Matrix}}$
APTES	Sn 4d, 1461	8	6.01	0.81
C ₃ NH ₈	Si 2p, 1384	~6	4.83	0.82

According to Table 1, the equation 4 can be simplified due to a ratio of the attenuation factors $k_{\text{Sn4d}}^{\text{APTES}}$ and $k_{\text{Si2p}}^{\text{C}_3\text{NH}_8}$ close to unity. Moreover, the kinetic energies of Si 2p and Sn 4d are closed together and in range where the variation of the transmission function is weak. Following these assumptions, the silicon surface concentration n_{Si} corresponding to the surface concentration of APTES molecules n_{APTES} can be described by:

$$\text{Eq. (6)} \quad n_{\text{APTES}} = n_{\text{si}} = \frac{I_{\text{Si}2p}}{I_{\text{Sn}4d}} \times \frac{\sigma_{\text{Sn}4d} N_{\text{Sn}} \lambda_{\text{Sn}4d}^{\text{SnO}_2} \cos \theta}{\sigma_{\text{Si}2p}}$$

It is worth noting that the main uncertainty on the estimation of APTES surface concentration comes from the electron collecting angle θ due to the roughness of the SnO₂ substrates.

However, results of atomic force microscopy measurement, not presented here, have shown comparable roughness for the three substrates used which allows comparing the three processes of silanization in terms of surface concentrations of grafted APTES molecules.

Calculations were carried out with Scofield cross section of 0.817 for $\sigma_{\text{Si}2p}$, 2.7 for $\sigma_{\text{Sn}4d}$ and using an atomic concentration per unit volume of Sn in SnO₂ of 2.77×10^{22} atoms/cm³. Table 2 reports the calculated covalently grafted APTES concentrations after the different synthesis ways of SnO₂-APTES (anhydrous and hydrous liquid and vapor silanization). All the SnO₂-APTES films were annealed after silanization at 110 °C, so no physisorbed APTES molecules present in the films.

Table 2. Calculated concentrations of APTES grafted on SnO₂ obtained by different synthesis ways.

	$n_{\text{APTES}} \text{ (molecules/cm}^2\text{)}$
SnO ₂ -APTES (vapor phase)	4.7×10^{14}
SnO ₂ -APTES (hydrous liquid)	9×10^{14}
SnO ₂ -APTES (anhydrous liquid)	4.24×10^{14}

The SnO₂-APTES carried out by liquid silanization in presence of 5 vol% H₂O indicates the highest n_{APTES} . This means that more APTES is present on the SnO₂ surface. The presence of H₂O hydrolyzes ethoxy groups of the APTES to silanol groups which enhances the condensation reaction with hydroxyl groups of SnO₂ and polymerization of APTES [17]. With vapor deposition and with liquid synthesis without water, the condensation is less favored due to the absence of water. In addition, vapor route and liquid silanization without water lead to almost the same concentration range ($n_{\text{APTES}} = 4.7 \times 10^{14}$ and $n_{\text{APTES}} = 4.24 \times 10^{14}$, respectively). Therefore,

hydrous solution may have promising role in the silanization process superior to vapor or anhydrous.

3.3. Thermal stability of APTES

To study the thermal stability of APTES, samples were in-situ annealed at 110 °C (synthesis annealing temperature), 200 °C, 300 °C and 400 °C for 4 h at a pressure of 5.10^{-9} mbar. The evolution of the intensities of N 1s, C 1s, Si 2p, and Sn 3d are presented in Fig. 8. The decrease of the N 1s peak intensity with temperature can be explained by the partial thermal degradation of amine group between 110 °C and 400 °C, while at 500 °C no more amine groups are present on the surface. The evolution of the intensity of C 1s peak suggests also a decrease in the amount of carbon on the surface upon thermal treatment which is related to the degradation of different carbon bonds. After 4 h treatment at 500 °C, a presence of carbon at the surface was still detected. This residual carbon was assigned to Si-CH₂ bonds as the annealing treatments show no effects on the intensity of the Si 2p peak. The intensity of Sn 3d peak depends on the attenuating APTES overlayer. The increase of the intensity of Sn 3d peak with temperature is consequently in accordance with the progressive degradation of the APTES film as the temperature increases. However, Sn 3d is still less intense for SnO₂-APTES heated at 500 °C than for pure SnO₂. This could be related to the remaining silicon layer on the base SnO₂ metal oxide surface. This study of APTES thermal stability on SnO₂ showed that APTES grafted molecules started to degrade at 110 °C; organic part was removed when heating while Si atoms stayed attached to SnO₂.

Fig. 8. Evolution of N 1s, C 1s, Si 2p and Sn 3d intensities in function of temperature for 4 h annealing treatment of SnO₂-APTES synthesized in vapor phase.

4. Conclusion

APTES was deposited via vapor and liquid phases on SnO₂ films to compare the synthesis effects. Liquid phase silanization with water clearly demonstrates more APTES grafting than vapor and liquid phase silanization without water. Water during the liquid phase silanization enhances the polymerization of APTES on the surface. Interestingly, 4 h reaction and 50 mM

were found to be sufficient to saturate the SnO₂ film by APTES molecules. Furthermore, thermal treatment of APTES film on SnO₂-APTES shows that the APTES start to degrade at temperature above 110 °C, while no notable change in the amount of silicon between 110 °C and 500 °C is observed. Amine groups had totally disappeared after heating the film at 500 °C. We have calculated the concentration of APTES by calculating the amount of Si on the surface. The number of Si atoms of SnO₂-APTES synthesized by liquid without water and vapor silanization is respectively 4.24×10^{14} atoms.cm⁻² and 4.7×10^{14} atoms.cm⁻², while it is 9×10^{14} atoms.cm⁻² with the addition of 5 vol% H₂O. In addition, the concentration of grafted APTES determined by XPS analyses are in good agreement with the previous ATR-FTIR results which confirm that the liquid route in the presence of water leads to more APTES grafting onto SnO₂ indicating an almost 50% improvement. Future research is needed to apply these promising initial results to more concrete applications in gas and bio sensors or related domains.
