Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

Abstract

A comparative study for 62 toxic chemicals based on the monthly collection of aerosol samples during 2015-2016 in two coastal cities at both the African (Bizerte, Tunisia) and European (Marseille, France) edges of the W Mediterranean basin is presented. Legacy polychlorinated biphenyls ($\Sigma_{18}\text{PCBs}$) and polychlorinated dibenzo-p-dioxins and dibenzofurans ($\Sigma_{17}\text{PCDD/Fs}$) show generally higher median levels at the African edge (2.1 and 0.2 pg m^{-3} , respectively) compared to the European coastal site (1.0 and 0.08 pg m^{-3} , respectively). Contrary, the “emerging” polybrominated diphenyl ethers ($\Sigma_{27}\text{PBDEs}$) median concentrations were higher in Marseille ($\sim 9.0 \text{ pg m}^{-3}$) compared to Bizerte ($\sim 6.0 \text{ pg m}^{-3}$). Different past usage and current emission patterns were found at both edges of the W Mediterranean, most probably linked to the respective different regulatory frameworks for toxic chemicals. Our results indicate that the total organic carbon (TOC) and/or the elemental carbon (EC) contents in the atmospheric aerosol may have a stronger effect than the total suspended particle (TSP) content as a whole on the spatial-temporal variability and the long-range atmospheric transport potential of the studied POPs. A “jumping” of the PBDE local atmospheric stocks from the NW European Mediterranean edge to the NW African coast seems to be possible under favorable conditions at present. While a higher PBDE median loading is estimated for Marseille area ($\sim 550 \text{ ng m}^{-2} \text{ y}^{-1}$) compared to Bizerte ($\sim 400 \text{ ng m}^{-2} \text{ y}^{-1}$), the median PCB and PCDD/F dry deposition fluxes were higher at the African site, resulting in a 3-fold higher toxic equivalent (TEQ) loading of dioxin-like pollutants ($400 \text{ pg TEQ m}^{-2} \text{ y}^{-1}$) compared to Marseille ($\sim 140 \text{ pg TEQ m}^{-2} \text{ y}^{-1}$) with potential implications for the aquatic organisms. However, the inhalation exposure assessment points to a minimum risk for human health at both sites.

49

50 Introduction

51

52 Atmospheric particulate matter has been recognized as a major environmental airborne
53 pollutant impacting human health and ecosystems.¹ A recent study performed in the
54 Mediterranean Sea supports the hypothesis that atmospheric aerosols can elicit a
55 number of toxic effects in marine organisms due to the presence of hydrophobic
56 contaminants intimately associated to the atmospheric particle phase.² High molecular
57 weight (HMW) polycyclic aromatic hydrocarbons (PAHs) and generally persistent
58 organic pollutants (POPs) such as polychlorinated dibenzo-p-dioxins and dibenzofurans
59 (PCDD/Fs) and polychlorinated biphenyls (PCBs) are among the contaminants
60 suspected to produce these hazardous effects.² In addition, POPs associated to the
61 atmospheric particle phase can be more resistant to atmospheric degradation processes
62 (e.g. photodegradation) increasing therefore their atmospheric residence times,
63 subsequent long-range atmospheric transport (LRAT) and potential exposure.² A first
64 step in order to elucidate the potential role of particle-bound POPs in toxic pathways
65 and to estimate their atmospheric dry deposition, considered as the main vector for the
66 introduction of the most hydrophobic contaminants in aquatic ecosystems, is their
67 accurate qualitative (congener specific distribution) and quantitative (environmental
68 concentration) determinations in the atmospheric aerosol. The legacy PCDD/Fs and
69 PCBs may lead to complex mixtures in the environment. However, the seventeen
70 2,3,7,8-chlorine substituted PCDD/Fs (i.e. seven PCDDs or “dioxins” + ten PCDFs or
71 “furans”) and the twelve dioxin-like PCBs (DLPCBs) named CBs-81, -77, -105, -114, -
72 118, -123, -126, -156, -157, -167, -169, -189, jointly considered as dioxin-like
73 pollutants, have received most of the attention due to their accumulation and toxic
74 effects in biota and humans.³⁻⁶ In addition, a set of non-dioxin-like PCBs, commonly

75 referred as indicator PCBs (IDPCBs), containing CBs-28, -52, -101, -138, -153 and -180
76 are often monitored due to their higher environmental concentrations and potential toxic
77 effects by different mechanisms of action.⁷⁻⁹ Other POPs with recognized toxicity too,
78 such as polybrominated diphenyl ethers (PBDEs) can add up to the “contaminant-
79 aerosol cocktail”.^{10,11} These pollutants have different sources in the environment.
80 PCDD/Fs can occur as unintentional by-products in a number of industrial processes
81 and domestic heating,^{12,13} while current emissions of PCBs are urban/industrial centers,
82 open burning of products containing PCBs, waste incinerations, accidental fires and re-
83 volatilization from environmental reservoirs.^{14,15} PBDE were mostly used (and still used
84 in some regions) as flame retardants and, contrary to PCDD/Fs and PCBs, are
85 considered as a first generation of “emerging contaminants” (only recently restricted).
86 Three PBDE commercial formulations were extensively used worldwide: the penta-
87 formulation (with predominance of BDE-47 and -99), the octa-BDE (with PBDE-183 as
88 one of the major components) and the deca-BDE (with BDE-209 predominating).¹⁶
89 These contaminants are globally banned by the Stockholm Convention of POPs
90 (including all PBDE formulations) and regulated by the Water and Marine Strategy
91 Framework Directives at European level (except for the octa- and deca-PBDE
92 formulations). However, still very little or no information exists on current base line
93 levels and stocks for many marine areas, even in environments under important
94 anthropogenic pressure like the Mediterranean Sea. This semi-enclosed environment of
95 high ecological and socio-economic relevance is largely impacted by POPs and related
96 contaminants.^{17,18,19} PCDD/Fs, PCBs and PBDEs are among the POPs found in the
97 atmospheric compartment from various NW Mediterranean coastal environments (from
98 rural to large cities),²⁰⁻²⁶ and the central/Eastern basin²⁷⁻³³, but also farther from the
99 coast in the entire Mediterranean Sea.³⁴⁻³⁶ The European Mediterranean coast is by far

100 the most studied and only few measurements (focussing in the SE Mediterranean) have
101 been carried out in the African Mediterranean edge.^{37,38} The atmospheric occurrence of
102 POPs over the NW Mediterranean African coast still largely unknown. In addition,
103 parallel observations at both the African and European margins of the Mediterranean
104 Sea have never been attempted to the best of our knowledge.

105 We report here results from 22 aerosol samples (total suspended particles, TSP)
106 simultaneously collected (once per month) in two urban coastal sites at both the African
107 and European edges of the W Mediterranean. The samples have been analysed for 62
108 toxic chemicals associated to the atmospheric aerosol. The main objectives of this study
109 are: (1) to establish base line atmospheric levels of three of the most toxic POPs
110 families (i.e. PCDD/Fs, PCBs, and PBDEs) in two reference urban coastal sites in the
111 European and African W Mediterranean and (2) to compare the status of pollution, to
112 estimate the atmospheric loading and potential exposure of those chemicals at both
113 edges of the W Mediterranean coast.

114

115 **Materials and Methods**

116

117 *Sampling and study areas*

118

119 Atmospheric aerosols samples (TSP) were simultaneously collected from March 2015
120 to January 2016 in two representative coastal locations under strong anthropogenic
121 pressure at both the African and European W Mediterranean Sea edges: the cities of
122 Bizerte (Tunisia) and Marseille (France) (Figure S1). The air was drawn through pre-
123 combusted quartz fiber filters (QFFs) placed in high volume air samplers (Tisch

124 Environmental, Inc, USA). The sampling volume ranged from ~ 1800 to $\sim 5000 \text{ m}^3$
125 depending on the site and sampling event (Table S1).

126

127 *Marseille*: Samples were collected at the roof ($\sim 10 \text{ m}$ AGL) of the Endoume Marine
128 Research Station ($43^\circ 16' 49.90'' \text{ N}$, $5^\circ 20' 57.32'' \text{ E}$) located at the water front and
129 around 4 km from the city center and the Marseille maritime terminal. Marseille can be
130 considered as a NW large coastal city of the Mediterranean basin (~ 1 million
131 inhabitants), inducing important car traffic and biomass burning. A detailed area
132 description has been reported elsewhere.³⁹⁻⁴¹ Briefly, Marseille hosts one of the most
133 important ports of the Mediterranean Sea (~ 88 million tonnes of goods handled per
134 year) and stands in the vicinity (40 km SE) of the large petrochemical and industrial
135 complex of Fos-Berre area (e.g. petroleum refining, cement factory, waste combustion
136 units, metallurgical industries). The region is well known for its intense photo-oxidative
137 pollution episode^{42,43} and several characteristic wind patterns, generally below 5 m s^{-1} ,
138 except during the Mistral events (NW strong wind, $20\text{-}30 \text{ m s}^{-1}$) which are frequent in
139 the area (100 days/year) (Figure S1)

140

141 *Bizerte*: Sampling was conducted on the roof top ($\sim 8 \text{ m}$ AGL) of the Faculty of Science
142 of Bizerte ($37^\circ 16' 0.5802'' \text{ N}$, $9^\circ 52' 49.875'' \text{ E}$) around 1 km far from the city center,
143 close to the Gulf of Bizerte shoreline and Bizerte lagoon water front (Figure S1). A
144 detailed sampling description is offered elsewhere.⁴⁴ Briefly, Bizerte is a medium-size
145 city ($\sim 127\,000$ inhabitants), located in the north of Tunisia, between the Mediterranean
146 Sea and the Bizerte lagoon. Even if agriculture and fishery activities are important in the
147 area, a considerable number of light and heavy industries (i.e., cement, plastic, textile,
148 mechanic and electronic, iron and steel metallurgy, petroleum refining and lubricants)

are present in the area.⁴⁴ Average temperature of 22 °C, with hot summer and mild spring, frequent (200 days per year) NW winds (average speed of 6–8 m s⁻¹) and precipitation episodes mostly in fall and winter months, characterized the climate of Bizerte area.⁴⁴

153

154 *Sample processing*

QFFs were lyophilized, weighed, and spiked with a suit of PCDD/Fs, PCBs, and PBDEs ¹³C-labeled standards prior to Soxhlet extraction (24h) with a n-hexane: DCM (9:1) mixture. Extracts were rota-evaporated and cleaned-up by using the “Dioxin Prep System-Florisil Version” (Supelco, Bellefonte, PA, USA). PCBs and PBDEs were collected in a first fraction by elution (100 mL of n-hexane) of the multilayer silica gel column coupled to a florisil column and a subsequent elution (40 mL of DCM) of only the multilayer silica gel column (prior removal of the florisil column). PCDD/Fs were obtained in a second fraction by elution of the florisil column with 50 mL of DCM. Final extracts were rota-evaporated to ~ 1 mL, transferred to vials, and dried under a gentle nitrogen steam. Fractions were reconstituted in a few microliters of the respective PCDD/F, PCB, and PBDE ¹³C-labeled injection standards prior to instrumental analysis (Text S1).

167

168 *Instrumental Analysis*

169

Samples were analysed for 17 PCDD/Fs (congeners 2,3,7,8-susbtituted), 18 PCBs (12 DLPCBs+6IDPCBs) and 27 PBDEs (Text S1). Quantification was carried out by isotopic dilution according to 1613 US EPA method⁴⁵ on a gas chromatograph (Trace GC ultra,

173 Thermo Fisher Scientific, Milan, Italy) coupled to a high resolution mass spectrometer
174 (DFS, Thermo Fisher Scientific, Bremen, Germany). The injection temperature was 260
175 °C and 1 μ L of extract was injected (splitless mode). GC separation of PCBs and
176 PCDD/Fs was achieved using a 60 m $\times$ 0.25 mm $\times$ 0.25 μ m DB-5MS column (Agilent
177 J&W, USA), while a 15 m $\times$ 0.25 mm $\times$ 0.10 μ m Rxi®-5Sil MS column (Restek, USA)
178 was used for PBDEs. Different oven temperature programs were used for each family of
179 analytes (Table S2). Positive electron ionization (EI+) was used operating in selected
180 ion monitoring (SIM) mode at 10,000 resolving power.

181

182 *Quality assurance / quality control (QA/QC)*

183

184 Clean QFFs were individually wrapped in aluminum foil, baked at 450 °C overnight,
185 weighted and then stored at -20 °C in double sealed plastic bags until used. Field blanks,
186 consisting on baked QFFs transported to the sampling area, mounted in the sampler, and
187 dismantled, were collected at both sites, stored and analysed concurrently with the
188 samples. After sampling, QFFs were wrapped in aluminium foil again and stored in the
189 dark at -20°C. Blank levels were generally low for the three POP classes compared to
190 their concentrations in the samples, ranging from 0.02 to 3.5 pg (PCDD/Fs), from not
191 detected (n.d.) to 150 pg (PCBs), and from n.d. to 530 pg (PBDEs) depending on the
192 congener and sample (Table S3). Laboratory blanks (1 blank per five-sample batch)
193 showed lower or similar levels to field blanks, so no contamination during sampling,
194 storage and analysis occurred. Results were blank corrected. Chromatographic peaks
195 were only considered when the ratio between the two monitored ions was within $\pm 15\%$
196 of the theoretical value, and the signal-to-noise (S/N) ratio > 3 (instrumental limit of

197 detection, LOD). Limits of quantification (LOQs) corresponded to $S/N \geq 10$. Calibration
198 curves were daily checked. Median LODs ranged from ~ 0.3 to ~ 1.1 pg (PCDD/Fs),
199 from 2.1 to ~ 8.3 pg (PCBs) and from ~ 1.1 to 32.5 pg (PBDEs) depending on the
200 compound and sample (Table S4). Median method recoveries (extraction-cleanup-
201 analysis) varied from 70 to 97 % (PCDD/Fs), from 83 to 110 % (PCBs) and from 60 to
202 120 % (PBDEs) (Table S5). Results were corrected by recoveries.

203

204 *TOC, EC determinations and statistical analysis*

205

206 Total organic carbon (TOC) content was determined in filter subsamples by high
207 temperature combustion (CHN analyser).⁴⁶ For the elemental carbon (EC)
208 determination, additional filter sub-samples were pre-combusted at 340 °C during 2 h
209 under oxygen flow⁴⁷ and then analysed as above indicated. STATA/SE 12.1 software
210 was employed for the statistical data analysis.

211

212 **Results and discussion**

213

214 *Concentrations in the atmospheric aerosol*

215

216 *Dioxin-like POPs*

217

218 $\Sigma 2,3,7,8$ -PCDD/F concentrations in the aerosols over Bizerte area (Tunisia) ranged
219 from 32 to 1100 fg m⁻³ (222 fg m⁻³, median) along the sampling period and were
220 generally higher than those over Marseille coastal area (France), varying from 31 to
221 1280 fg m⁻³ (83 fg m⁻³, median) (Figure 1A). The highest differences were found for the

months of April, July and September 2015 (3, 11, ~5-fold higher levels in Bizerte, respectively). However, these values were not significantly different (Mann-Whitney test, $p=0.28$) for the sum of 2,3,7,8-PCDD/Fs most probably due to the high annual variability, in particular in Bizerte site, and the limited number of samples analysed. Significant differences were only found for two furan congeners (i.e. 2,3,4,6,7,8-HxCDF and 1,2,3,4,6,7,8-HpCDF) (Mann-Whitney test, $p=0.04$) (Figure S2, Table S6). A general trend showing higher PCDD/F levels in the coldest months of the year was observed at both sites. This effect has been previously reported in other Mediterranean coastal areas and has been attributed to the combined effect of the increase of diffusive combustion sources (e.g. domestic heating and road traffic) and a less efficient dispersion of the local emissions during cold conditions.²³ The Σ 2,3,7,8-PCDD/F was clearly dominated by the contribution of PCDDs in Marseille whereas a more even contribution of PCDDs and PCDFs was found for the aerosols of Bizerte area (Figure 1A), pointing to different PCDD/F sources at both sites. This is the first time that PCDD/Fs have been measured in atmospheric aerosols from the Marseille area and in a coastal site at the African Mediterranean edge. The concentrations found at both sites are within the range of those previously reported for a coastal area in the Gulf of Lion (50-1500 fg m⁻³)²³, urban/industrial sites from Barcelona area (570-1162 fg m⁻³)²⁴ and in the open NW Mediterranean (94-990 fg m⁻³).³⁵ Reported values from a cruise transect close to the NW Mediterranean African coast (38 fg m⁻³) are lower than those measured in Bizerte coastal area.³⁵ Concentrations measured in a background site in Barcelona area (230 fg m⁻³) are lower too than those in Marseille²⁴. No data for comparison was found in the central/eastern Mediterranean Sea. Recent PCDD/F measurements carried out in the atmospheric aerosol over remote areas

246 from the Atlantic, Pacific and Indian oceans revealed 6 to 11-fold lower background
247 levels (5 to 113 fg m⁻³).⁴⁸

248

249 The $\sum_{18}\text{PCB}$ concentrations measured in the aerosols from Bizerte, ranging from 0.7 to
250 ~ 4.0 pg m⁻³ (2.1 pg m⁻³, median) were significantly higher (Mann-Whitney test, $p=0.03$)
251 than those measured in the aerosols over Marseille, which varied from 0.5 to 2.7 pg m⁻³
252 (1.0 pg m⁻³, median). IDPCBs dominated the total levels at both sites with $\sum_{\text{ID}}\text{PCB}$
253 concentrations significantly higher too in Bizerte (0.6 to 3.4 pg m⁻³, median value of $\sim$
254 2.0 pg m⁻³) than in Marseille (0.3 to 1.8 pg m⁻³, median value of 0.8 pg m⁻³) (Mann-
255 Whitney test, $p=0.01$) (Figure 1B). $\sum_{\text{DL}}\text{PCB}$ concentrations, which represented a minor
256 contribution to the total PCB atmospheric stock at both sites, were not statistically
257 different (0.1 - 0.5 pg m⁻³ in Bizerte compared to 0.1 - 0.8 pg m⁻³ in Marseille).
258 However, the concentrations of some of the most toxic DLPCBs (i.e. CB-81, -126, -169)
259 as well as the CBs-167, -189 were significantly higher in Bizerte than in Marseille
260 coastal area (2-4 fold-higher median values depending on the congener) (Figure S3,
261 Table S7).

262 $\sum_{18}\text{PCB}$ (and $\sum_{\text{ID}}\text{PCB}$) concentrations exhibited different annual trends in both sites.
263 While a general increase of concentrations was observed in winter months compared to
264 spring and summer in Marseille, a more pronounced seasonality was observed for
265 Bizerte, showing clearly higher concentrations in spring-early summer and late autumn-
266 winter months, with minimum levels in August, September and October (Figure 1B). As
267 a result, 2 to 8-fold higher $\sum_{18}\text{PCB}$ levels were measured in Bizerte than in Marseille
268 from March to July while the concentration differences between the two sites in winter
269 months were less important, and in some months (e.g. November) higher for Marseille.
270 Interestingly, higher $\sum_{\text{DL}}\text{PCB}$ concentrations were generally measured from August

2015 to January (except in December) in Marseille. These facts highlight the differential environmental behaviour, seasonality and related exposure of individual PCBs at both sites.

PCB data comparability may be tricky since different number and type of PCBs may be considered. Therefore, for comparative purposes we focus only on $\Sigma_{ID}PCB$ concentrations measured at both edges of the NW Mediterranean Sea were generally lower than previous coastal measurements performed in the NW Mediterranean in the Gulf of Lion (0.5 to 7.2 pg m^{-3})^{23,26} and those carried out close to Barcelona area (9 - 26 pg m^{-3}).²⁶ Cruise measurements encompassing the Mediterranean Sea and the SW Black Sea in 2006 and 2007 revealed higher concentrations too for $\Sigma_{ID}PCB$ (0.4 - 18 pg m^{-3}), but PCB-118 was included in the sums.³⁶ However, concentrations measured in Bizerte and Marseille were generally higher than those reported for a coastal site (considered as a background location) in the Eastern Mediterranean²⁷ consistent with previous studies indicating higher PCB levels in the W Mediterranean.³⁶ Most of the previous studies correspond to measurements performed more than a decade ago (as for PCDD/Fs) so comparison must be done carefully. Particle-bound PCBs have received little attention since then in the Mediterranean basin compared to gas phase PCBs, most probably due to the dominant role of vapor PCBs driving total PCB ambient levels (especially for low MW congeners) and the increasing applications of passive sampling techniques to POP atmospheric measurements. Thus, recent studies in the Mediterranean Sea considered only the gas phase or the assemble gas+particle phases.^{32,33} $\Sigma_{DL}PCB$ background measurements in the atmospheric aerosol over remote areas from the Atlantic, Pacific and Indian oceans revealed up to 500-fold lower levels (1 - 2675 fg m^{-3}).⁴⁸

These figures confirmed that the NW Mediterranean Sea is considerably exposed to dioxin-like POPs, and might act in turn as a potential secondary source, in particular of

PCBs, for other Mediterranean regions (less exposed) and for the most pristine areas of the major oceans of the Earth. It has been reported that the principal control on the levels of legacy POPs in active circulation in the global environment is currently in a state of transition (from primary to secondary source control).¹⁴ The role of the NW Mediterranean Sea (and other similar impacted marine areas) as potential secondary sources at present remains uncertain and requires further investigation.

303 **Figure 1.** Temporal variability of PCDD/F (A), PCB (B) and PBDE (C) concentrations
304 in atmospheric aerosols over Marseille (MA) and Bizerte (BZ) coastal areas from March
305 2015 to January 2016.

306

307 *PBDEs*

308

309 Σ_{27} PBDE concentrations were generally higher than dioxin-like POPs (in particular
310 compared to PCDD/Fs) at both sites. Levels in the aerosol from Bizerte ranged from 1.0
311 to 54.0 pg m⁻³ (~ 6.0 pg m⁻³, median), while in Marseille varied from 2.2 to 17.6 pg m⁻³
312 (~ 9.0 pg m⁻³, median) (Figure 1C). A general trend of higher levels in Marseille area
313 was found, with the exception of the samples collected in spring in Bizerte, in particular
314 the one of March 2015 (which exhibited 3 to ~50-fold higher PBDE levels than the rest
315 of samples collected in Bizerte). This concentration peak can be attributed to an unusual
316 higher concentration of medium-high MW PBDEs in that sample compared to the
317 others, in particular BDE-183 (Table S8), likely due to the combined effect of the air
318 mass back trajectories (BTs) and potential local sources during this sampling event (see
319 discussion below). However, the concentrations at both sites did not show a statistical
320 difference (Mann-Whitney test, $p>0.05$). Still, some individual congeners exhibited
321 statistical differences but with contrasting trends, like BDE-47 with 3-fold higher
322 median concentrations in Marseille than Bizerte (Mann-Whitney test, $p=0.01$), while
323 BDE-3, -7, -71, -77, -126, and -156 showing higher levels in the aerosols from Bizerte
324 ($p<0.01 - 0.04$) (Figure S4, Table S8). PBDE-209 was the major contributor to the total
325 Σ_{27} PBDE for most of the samples at both sites (Figure 1C).

326

327 Σ_{27} PBDE concentrations measured in Marseille and Bizerte were generally within the
328 range of those reported for a coastal site in the NW Mediterranean ($2\text{--}18\text{ pg m}^{-3}$,
329 Σ_8 PBDE)²³, higher than levels in a coastal background site in central/E Mediterranean
330 ($0.5\text{--}2\text{ pg m}^{-3}$, Σ_{15} PBDE)³⁰ but in the lower end of values reported for aerosols collected
331 over large cities in the E Mediterranean like Athens (Greece) ($15\text{--}23\text{ pg m}^{-3}$,
332 Σ_{12} PBDE)²⁹ and Izmir (Turkey) ($27\text{--}62\text{ pg m}^{-3}$, Σ_7 PBDE).³⁸

333

334 *POPs patterns in the atmospheric aerosol*

335

336 The PCDD/F atmospheric pattern (congener relative contribution) for most of Bizerte
337 samples showed an important contribution of furans, with 1,2,3,4,6,7,8-HpCDF and
338 OCDF accounting for the $16.3\pm 3.7\%$ and $12.2\pm 7.3\%$ of the $\Sigma_{2,3,7,8}$ -PCDD/F, values
339 almost reaching the relative contribution of 1,2,3,4,6,7,8-HpCDD ($17.0\pm 4.0\%$) and
340 OCDD ($25.5\pm 4.5\%$) which are the two most abundant PCDDs (Figure 2A-1). However,
341 the PCDD/F pattern in samples from Marseille was dominated by a higher contribution
342 of 1,2,3,4,6,7,8-HpCDD ($21.2\pm 6.8\%$) and OCDD ($53.0\pm 4.0\%$) and lower contribution
343 of 1,2,3,4,6,7,8-HpCDF and OCDF accounting for the $5.8\pm 3.0\%$ and $6.0\pm 2.8\%$ of the
344 $\Sigma_{2,3,7,8}$ -PCDD/F, respectively (Figure 2A-2). A higher contribution of PCDFs in the
345 PCDD/F atmospheric pattern compared to PCDDs has been associated in previous
346 studies to ‘fresh’ emissions (sources). A situation in which the lower chlorinated
347 congeners, in particular PCDFs, have insufficient time to experience significant
348 atmospheric degradation / depletion processes.^{23,35,49,50} Contrary, a predominance of
349 higher chlorinated PCDDs and little contribution of PCDFs is considered as a ‘sink’
350 signal where the lighter congeners were ‘weathered’ in their travel from the source to
351 the sampling sites due to atmospheric processes (e.g. photodegradation).

352 These patterns suggest current local PCDD/F emission in Bizerte in combination with a
353 minor contribution of long/medium-range atmospheric transport of PCDD/Fs to the
354 area. Contrary, the long/medium range atmospheric transport seems to drive the
355 atmospheric occurrence of PCDD/Fs in Marseille area with a minor contribution of
356 local sources. The possibility of short-range atmospheric transport from the adjacent
357 industrial areas (Fos-Berre) to Marseille with known sources of PCDD/Fs (e.g. from
358 incinerators, metallurgical and petrochemical facilities) is not excluded. Nevertheless,
359 because of the surrounding topography of Marseille, bordered by the Mediterranean
360 from the SW and enclosed from N, E and S by mountain ranges up to ~700m ASL,
361 direct transport from the Fos-Berre area to Marseille is rarely observed. Such transport
362 could occur when the wind is a composition of land/sea breeze and light Mistral but the
363 air mass will go towards the sea before to come back to Marseille which corresponds to
364 a half-range atmospheric transport. Furthermore, these wind conditions correspond
365 generally to sunny period inducing strong photochemical processes.^{39-41,43}

366

367 The PCB atmospheric pattern was dominated in general by the HMW _{ID}PCBs at both
368 sites. A clear predominance of PCB-180 in Bizerte (accounting for the 35.0±8.7 % of
369 the $\sum_{18}$ PCBs) was observed compared to Marseille area (19.2±5.1 % of the $\sum_{18}$ PCBs).
370 A similar pattern was observed in the two sites for _{DL}PCB, but PCB-118 and -105
371 predominated in Marseille (12.6±3.2% and 5.7±1.8%, respectively) compared to Bizerte
372 (4.6±2.0% and 1.9±0.5%, respectively). The different abundance of these three major
373 PCBs may be either the reflect of different past usage of PCB commercial mixtures at
374 both sites or distinct emissions rates to the environment at present. For example, PCB-
375 180 is one of the major constituent of Aroclor 1260 and 1262, while CB-105, 118 were
376 relatively more abundant in the Aroclor 1254 formulation. One of the major uses of

these Aroclor formulations was as industrial oils destined to transformers.⁵¹ It has been very recently reported that a large number of transformers containing PCBs are still used or stored in unsatisfactory conditions in Bizerte area with high probability of oil leaks.⁴⁴ This could explain the higher contribution of PCB-180 in Bizerte compared to Marseille.

Figure 2. Average atmospheric pattern (n=11) of PCDD/F (A) and PCBs (B) in Marseille (MA) and Bizerte (BZ) coastal areas. The small figures (1) and (2) show a

386 focus on the differences in the atmospheric pattern found in Bizerte (dominated by a
387 characteristic “source pattern”, n=7) and in Marseille (dominated by a characteristic
388 “sink” pattern, n=9).

389

390 The predominance of BDE209 was reflected also in the atmospheric congener pattern
391 (Figure 3) accounting for the $72.3 \pm 18.6\%$ and $65.5 \pm 18.0\%$ of the $\Sigma_{27}\text{PBDE}$ in Marseille
392 and Bizerte, respectively. The important abundance of this BDE denotes the past and
393 maybe current usage of deca-PBDE formulations at both edges of the NW
394 Mediterranean Sea.¹⁶ In addition, the predominance of BDE-47 and BDE-99 in the
395 pattern from Marseille samples too, together with their higher abundance ($6.8 \pm 7.3\%$ and
396 $5.3 \pm 4.5\%$ for BDE-47 and -99, respectively) compared to the pattern in Bizerte (2.0
397 $\pm 1.9\%$ and $2.8 \pm 2.5\%$ for BDE-47 and -99, respectively), point first to a major usage of
398 penta-PBDE compared to the octa-PBDE formulations in Marseille. Second, to a
399 different emission and usage pattern compared to Bizerte, where a major usage of octa-
400 PBDE formulations may be the most likely scenario represented by a higher BDE-183, -
401 206, -207 predominance in Bizerte reaching up to 31.6, 9.1 and 13.8% of the $\Sigma_{27}\text{PBDE}$,
402 respectively.

403

Figure 3. Average atmospheric pattern (n=11) of PBDEs in Marseille and Bizerte coastal areas.

Factors affecting temporal and spatial variability

The finest fractions of the atmospheric TSP, like TOC and EC, have been reported to efficiently sorb POPs-like contaminants.^{29,52-53} Generally higher median concentrations of TSP (66.0 ug m^{-3}), TOC (7.5 ug m^{-3}) and EC (2.0 ug m^{-3}) were measured in the aerosols over Bizerte compared to Marseille area, exhibiting 48.0 , 6.4 and 0.9 ug m^{-3} of TSP, TOC and EC, respectively. However, only significant differences (Mann-Whitney test, $p=0.03-0.006$) were found for the TSP and EC (Figure S5). No correlations were found for PCDD/F concentrations and TSP levels in any of the sites and only $\sum_{18}\text{PCB}$, $\sum_{10}\text{PCBs}$ and one PCB congener correlated ($p=0.01-0.04$) with TSP concentration in Bizerte (Figure S6). $\sum\text{PCDD/F}$ and $\sum_{\text{DL}}\text{PCB}$ (as well as most of PCDD/Fs and a certain number of DLPCBs) concentrations positively correlated with TOC concentration

($p=0.004-0.03$) but not with EC levels in Marseille. Only 2,3,7,4-TCDD positively correlated with TOC concentrations in Bizerte and no correlations were observed for DLPCBs and TOC in Bizerte. Interestingly, PCDD/F concentrations were not correlated with EC levels in any of the sites, while $\sum \text{DLPCBs}$, $\sum_{18}\text{PCB}$ and $\sum \text{IDPCBs}$ were correlated with EC mostly in Bizerte ($p=0.002-0.01$), most probably due to the higher EC levels in this site. $\sum_{27}\text{PBDE}$ concentrations did not significantly correlate with TSP, TOC or EC in any of the sites. However, while only two individual PBDEs correlated with TSP levels (Bizerte) a considerable number of PBDE congeners were correlated with TOC concentrations in Marseille and with EC levels in Bizerte (Figure S7). The fact that PCDD/Fs did not correlate with EC is somehow unexpected since this correlation has been suggested in other atmospheric studies.^{54,55} The narrow range of variation of EC concentrations in the samples analysed could have resulted in this lack of correlation. Regarding TOC, the correlations mostly observed for Marseille could be the result of different TOC sources (different sorption properties) in both sites (e.g. more related to urban activities in Marseille and predominantly industrial activities in Bizerte).

436

Our results indicate that the TOC and/or EC contents in the atmospheric aerosol may have a stronger effect than the TSP as a whole on the spatial-temporal variability of the studied POPs. Concentrations normalized by TOC slightly decreased the $\sum_{2,3,7,8}\text{PCDD/F}$, $\sum_{18}\text{PCB}$, $\sum \text{IDPCBs}$ and $\sum_{27}\text{PBDE}$ annual variability at both sites (except for the month of January 2016) and confirmed the similar spatial variability with no significant differences for PCDD/Fs ($p=0.67$) and PBDEs ($p=0.66$) and higher levels of $\sum_{18}\text{PCB}$ (although not significant, $p=0.07$) and $\sum \text{IDPCBs}$ ($p=0.03$) in Bizerte (Figure S8). The higher concentrations in January 2016 resulted in 4 to 9-fold higher levels in

445 Bizerte (412, 1050, 154 and 3210 ng g_{TOC}⁻¹) compared to Marseille (80,113, 51 and 811
446 ng g_{TOC}⁻¹) for $\Sigma_{2,3,7,8}$ -PCDD/F, $\Sigma_{\text{ID}}\text{PCB}$, $\Sigma_{\text{DL}}\text{PCBs}$ and $\Sigma_{27}\text{PBDE}$, respectively. In
447 addition, an increase of the concentration differences (normalized by TOC) compared to
448 their respective volumetric concentrations was found for $\Sigma_{\text{DL}}\text{PCBs}$ in March 2015.

449

450 Concentrations normalized by EC (Figure S9) showed predominant levels of $\Sigma_{2,3,7,8}$ -
451 PCDD/F for Marseille in March 2015 and January 2016 (where the lowest
452 concentration of EC were measured) and confirmed the $\Sigma_{18}\text{PCB}$ and $\Sigma_{\text{ID}}\text{PCB}$ higher
453 levels in Bizerte during spring-early summer compared to Marseille, but pointed to
454 generally higher concentrations in Marseille from September to winter. Interestingly, a
455 statistically significant ($p < 0.01$) predominance of $\Sigma_{\text{DL}}\text{PCB}$ levels in Marseille resulted
456 from the normalization by EC, which was not verified as volumetric or TOC normalized
457 concentrations. The same effect ($p < 0.001$) was observed for the $\Sigma_{27}\text{PBDE}$, exhibiting
458 higher levels in Marseille for all months (7.4 ug g_{EC}⁻¹, median value) than in Bizerte
459 (3.0 ug g_{EC}⁻¹, median value) with clear peak differences in August and September.

460

461 Four-day BTs were calculated (50, 500 and 1000m AGL) by using the HYSPLIT
462 model⁵⁶ (Figure S10). The lowest $\Sigma_{2,3,7,8}$ -PCDD/F levels were registered in the
463 months of June, July and August 2015 in Marseille, where air masses had a clear
464 Atlantic influence, while the highest level was measured in the month of January 2016
465 with air masses showing continental influence (Figure S9). A similar min-max temporal
466 pattern was observed in Bizerte, with lower levels in summer months (except for July)
467 than in January. However, the BTs in July revealed a more important continental
468 influence for Bizerte compared to Marseille. $\Sigma_{18}\text{PCB}$ concentrations had minimum level
469 in April 2015 over Marseille, with air masses mostly circulating over the W

470 Mediterranean waters and peaked also in January 2016. The lowest $\sum_{18}\text{PCB}$
471 concentrations were measured in October in Bizerte, whereas the higher levels
472 correspond to April 2015 (with air masses circulating over the Bizerte area and the
473 African continent) consistent with suspected current local PCB emissions.

474 Interestingly, $\sum_{27}\text{PBDE}$ exhibited the lowest concentrations in the months of March
475 2015 over Marseille, with air masses showing an important component coming from the
476 N African coast, while the highest concentrations were measured in the same month in
477 Bizerte, with air masses showing the 50m height component coming from the Gulf of
478 Lion area. Recent reports have shown evidences of the North to South atmospheric
479 particle transport over some regions in the NW and E Mediterranean Sea^{57,58}. In
480 addition, PBDEs have been described to be mostly associated to the finest particles of
481 the atmospheric aerosol²⁹, consistent with the correlations found with the TOC and/or
482 EC contents (more abundant and stronger) compared to the TSP as discussed above.
483 This will result in higher atmospheric residence times and a higher potential of LRAT.
484 These facts may support the hypothesis of the potential “jumping” of PBDE local
485 atmospheric stocks from the NW European Mediterranean edge to the NW African
486 coast (where lower PBDE ambient levels has been generally measured) under favorable
487 conditions. Indeed, the two sites are relatively close (around 780 km straight line).
488 However, this hypothesis requires further confirmation with more sites at both edges of
489 the NW Mediterranean. In addition, a better characterization of PBDE local sources
490 (emission inventory) at the African edge is needed. The BT analysis reveals too other
491 potential hot spots farther west in the N African coast which find their way to Bizerte
492 area passing through the Gibraltar strait and along the African cost, as observed in the
493 month of May 2015. The three POP families exhibited higher levels in Bizerte area
494 compared to Marseille (with a different air mass circulation pattern) in this month. This

situation has been previously described for PCDD/Fs³⁵ and PAHs¹⁸ in the same region. BTs could only explain part of the annual and spatial variability for the studied POPs, most probably due to their different environmental sources and current local emissions patterns (mostly for legacy POPs) at the studied sites as discussed above, which may prevail over the BT influence at a local/regional scale in different seasons of the year. In addition, other parameters affecting the atmospheric gas-particle partitioning of POPs (e.g. temperature, relative humidity) may have an important influence at local scale.

Atmospheric dry deposition and exposure

Dry deposition fluxes (F_{DD} , $\text{pg m}^{-2} \text{ d}^{-1}$) of PCDD/Fs, PCBs and PBDEs were calculated as:

$$F_{DD} = v_d C_A \quad [1]$$

where C_A is the POP volumetric concentration in the aerosol (pg m^{-3}) and v_d (cm s^{-1}) is the particle deposition velocity. A reference value of 0.2 cm s^{-1} for v_d was adopted for both sites. This value is within the range of v_d experimentally measured⁵⁹ or previously used in coastal NW Mediterranean Sea^{23,35,36} for the estimation of dry deposition fluxes of POPs. However, a degree of uncertainty is associated to this calculation due to the lack of v_d measurements during the sampling events.

Overall, the atmospheric loading at both coastal areas is dominated by PBDEs, ranging from 70 to $\sim 3400 \text{ ng m}^{-2} \text{ y}^{-1}$, followed by PCBs (30 to $\sim 250 \text{ ng m}^{-2} \text{ y}^{-1}$) and PCDD/Fs (2 to $80 \text{ ng m}^{-2} \text{ y}^{-1}$) as expected from their relative atmospheric concentrations and the assumptions considered in these calculations (Table 1, S9-S11). These fluxes were

generally within the range of previously reported dry deposition estimations in the Mediterranean and SW Black Sea for the same POPs^{23,28,35}. However, some differences were found in the atmospheric loading at both edges of the Mediterranean Sea. While a higher PBDE median loading is estimated for Marseille area ($\sim 550 \text{ ng m}^{-2} \text{ y}^{-1}$) compared to Bizerte ($\sim 400 \text{ ng m}^{-2} \text{ y}^{-1}$), the median dry deposition fluxes of PCBs ($135 \text{ ng m}^{-2} \text{ y}^{-1}$, and PCDD/Fs ($14 \text{ ng m}^{-2} \text{ y}^{-1}$) in Bizerte were higher than those of Marseille, ~ 60 and $5 \text{ ng m}^{-2} \text{ y}^{-1}$, respectively. Indeed, a 3-fold higher loading of dioxin-like pollutants was estimated for Bizerte as toxic equivalents (TEQ)⁶⁰ ($400 \text{ pg TEQ m}^{-2} \text{ y}^{-1}$, median) compared to Marseille ($137 \text{ pg TEQ m}^{-2} \text{ y}^{-1}$, median) due to a higher contribution of PCDFs and DLPCBs in Bizerte (Table 1). These figures indicate a higher potential exposure to these toxic chemical at the African edge of the W Mediterranean. Considering $1.6 \times 10^{10} \text{ m}^2$ as the surface of the Gulf of Lion⁶¹ and an equivalent surface in the surroundings of Bizerte in the African coast, from 9 to 10 kg of POPs can be annually loaded (median value) to surface waters at both edges of the Mediterranean associated to the atmospheric aerosol. The sensitive environment of Bizerte coastal lagoon ($1.28 \times 10^8 \text{ m}^2$)⁶² could receive up to 0.5 kg of POPs yearly. This loading of toxic chemicals may have implications for the aquatic organisms but this evaluation cannot be performed with the present data. However, it should be further investigated.

538

A human health risk assessment for the whole set of dioxin-like POPs was performed based on the inhalation exposure. We follow here a similar approach as a very recent assessment based on only two dioxin-like PCBs performed in Bizerte area⁴⁴. Briefly, concentrations expressed as WHO_{05} TEQ were calculated using the latest available toxic equivalency factors (TEFs).⁶⁰ A daily air inhalation volume of 15 m^3 for an adult of 60 kg was assumed.⁶³ The $\Sigma 2,3,7,8\text{-PCDD/F}$ and $\Sigma_{\text{DL}}\text{PCB}$ concentrations in the

aerosols over Bizerte area, ranged from 0.7 – 70.2 and 0.07 - 2.2 WHO₀₅ TEQ fg m⁻³, respectively, whereas in Marseille levels varied from 0.4 – 23.0 and 0.03 to 0.3 WHO₀₆ TEQ fg m⁻³, respectively. Median TEQ values (for all dioxin-like congeners) of 6.3 and 2.2 WHO₀₅ TEQ fg m⁻³ (Bizerte and Marseille) would result to potential intakes of 0.002 and 0.001 pg TEQ kg⁻¹ day⁻¹, respectively. Both levels are three orders of magnitude lower than the daily intake threshold of 1-4 pg TEQ kg⁻¹ day⁻¹ propose by WHO⁶⁴. The atmospheric particle phase PCDD/F concentration can be considered as a good descriptor of the total atmospheric concentration due to their general predominance in this compartment after their emissions to the environment.^{22,23,35,49} Contrary, PCBs show a general preferential partitioning (mostly low MW congeners) to the vapour phase.^{36,48} However, according to filed measurements performed in various urban, coastal and remote Mediterranean environments and inland aquatic ecosystems the $\Sigma_{DL}PCB$ gas phase concentrations are not expected to exceed more than 100 fold the measured particulate phase concentrations.^{23,27,36,63,65} Therefore, the worst case $\Sigma_{DL}PCB$ TEQ concentration could be estimated as 100 fold the TEQ calculated considering only the particle-bound PCB concentrations, resulting in a corrected daily intake (for all dioxin-like congeners) of 0.01 and 0.004 pg TEQ kg⁻¹ day⁻¹ in Bizerte and Marseille areas, respectively. This new value stills far below the daily intake threshold proposed by WHO and therefore a risk by the inhalation route is excluded at present in the studied areas. It should be noted thought that the daily intake threshold proposed by WHO is based on toxicity studies evaluating dose-response through oral exposure. However, absorption and tissue partitioning could be different via the inhalation route and the local toxicity effect to lungs is not considered, so there is still an uncertainty degree in this assessment.

569 There are no TEFs associated to PBDEs and according to the European Chemicals
570 Agency, the risks of deca-BDE and lower brominated transformation products to the
571 humans via the environment cannot be adequately addressed in a quantitative way due
572 to the high uncertainties regarding long-term exposure and effects.⁶⁶ Similarly to
573 PCDD/Fs, PBDE particle-bound atmospheric concentrations can be a good indicator of
574 the total atmospheric levels, particularly considering that one of the most abundant
575 PBDEs is the HMW PBDE-209 (almost exclusively in the particle phase). For example,
576 the PBDE particle-bound fraction in a large Mediterranean city (Athens, Greece)
577 exhibiting similar atmospheric TSP concentration as Marseille and Bizerte accounted
578 from more than the 70% of the total airborne PBDE concentrations.²⁹ Following the
579 above calculations, median intakes of 1.6 and 2.2 pg kg⁻¹ day⁻¹ were estimated for
580 Bizerte and Marseille, respectively. As a reference, three order of magnitude higher
581 (~7.0 ng kg⁻¹ day⁻¹) PBDE intakes has been reported for American adults.⁶⁷ However,
582 the exposure to PBDE has been mostly associated to indoors environments (mainly dust
583 ingestion and dermal contact)⁶⁷ and inhalation is not considered as the main route of
584 concern for these substances.
