ABSTRACT

In order to characterise the behaviour of concrete under high pressures and high strain-rates, dynamic 1D-strain compression tests were performed. A cylindrical specimen is embedded in a steel confinement ring and compressed between 2 cylindrical plugs with a SHPB (Split Hopkinson Pressure Bars) device. Moreover, a new method was used to process the experimental data. It is based on numerical simulations of the cell loaded by an internal pressure that allow to build a relation between the pressure applied by the concrete to the inner surface of the cell and the external hoop strain measured by gauges. Stresses and strains in the specimen are computed at any loading time and the evolution of the deviatoric stress versus the pressure (deviatoric behaviour) and of the pressure versus volumetric strain (spherical behaviour) is deduced. The method is validated by several numerical simulations of the test involving different friction coefficients between the cell and the specimen.

Three 1D-strain compression tests were performed and processed with the MB50 high-performance concrete. They showed that the deviatoric and spherical behaviours are almost independent of the strain rate in the observed range of strain rates (80-221 s⁻¹). The deviatoric strength is seen to increase regularly with the hydrostatic pressure. The spherical behaviour indicates a fairly constant dynamic modulus of compressibility (around 5 to 6 GPa) up to a pressure of 900 MPa.

Introduction

The compaction of concrete associated with a volume decrease over 10% occurs under high pressures. Such situations are found in military applications (blast loading, penetrating projectile) or in studies for the safety of buildings (power plants) regarding an accidental internal loading or external loading (plane crash). In such situations, a compressive loading, with high pressures (up to 1000 MPa) and high strain-rates (up to some hundreds of s⁻¹), is produced.

The use of the compressive Split Hopkinson Pressure Bar (SHPB) to determine the rate sensitivity of concrete can be found in recent works [1-5]. However, the test analysis must consider both material and structural aspects. For example, the increase of the stress with the strain rate can be due to the radial confinement induced by inertial effect and/or by the intrinsic rate sensitivity of the material. Indeed, for a material with a non-zero Poisson's ratio, the lateral expansion associated with the compression is restrained by inertia effects [6-9]. As rock-like materials are very sensitive to the lateral pressure when they are axially loaded, they can show artificial apparent strain-rate sensitivity. In the present case, the confinement cell considerably reduces the radial displacement and the radial pressure due to inertia is not acting. Dynamic axial compression testing with lateral pressure is not so common. For lower lateral pressures, experimental data are obtained using a SHPB axial loading system combined with a pressure cell [5, 10, 11, 12]. This technique does not allow for the high pressures required for compaction.

A new testing device of confined compression has been designed and used in the case of quasi-static loading in [13], involving axial and lateral stresses in the range of expected dynamic values. In the present work, an analogous technique is used in the

dynamic range using a SHPB to produce an axial loading and to measure axial forces and displacements. First, the principle of the 1D-strain compression test is presented. The methodology of processing the data is detailed next. It is validated by means of several numerical simulations for which the methodology of processing the experimental data is employed. In particular, influence of friction between the specimen and the cell is pointed out. Finally, the methodology is used to analyse three 1D strain compression tests performed by Split Hopkinson Pressure Bars.

Principle of quasi-oedometric compression tests

The principle of the test is described in Figure 1. A cylindrical specimen (diameter: 30 mm, length: 40 mm) is embedded in an instrumented steel confinement ring (Fig. 1b, outer diameter: 65 mm, length: 45 mm) and is compressed between 2 cylindrical plugs (Fig. 1a). A gap, about 0.2 mm thick, is left between the concrete specimen and the ring. It is filled with an epoxidic resin, coated with Teflon. This material is highly incompressible and it does not reduce the confinement pressure. It also has a weak shear behaviour allowing for easier relative displacements between the ring and the specimen. Three hoop strain gauges were glued on the external surface of the metallic ring (Fig. 1b). From the corresponding measurements, it is expected to deduce the radial stress and strain within the specimen. One gauge is located in the middle of the ring (n°2) and the two others (n°1 and 3) are located at a distance from the middle equal to $\frac{3}{4}$ of the half-length of the ring (Fig. 1b). Three axial gauges (n°4, 5, 6) are located on the same axial planes (Fig. 1b). From their measurements, it is expected to compute the barrelling of the ring.

A SHPB is used to produce a dynamic axial loading (Fig. 1c). It is composed of the long input (or incident) and output (or transmitter) bars with a short specimen placed between them. With the impact of a projectile (or striker) at the free end of the input bar, a compressive longitudinal "incident" wave $\varepsilon_I(t)$ is created in the input bar. Once the incident wave reaches the interface specimen-bar, a reflected pulse $\varepsilon_R(t)$ in the input bar and a transmitted pulse $\varepsilon_T(t)$ in the output bar are developed. With the gauges that are glued on the input and output bars (A and B, Fig. 1c), these three basic waves are recorded. Their processing allows for the knowledge of forces and particle velocities at both faces of the specimen [14]. The cell and its plugs are inserted between the two Hopkinson bars. The loading produces a compression of the concrete and a subsequent increase of the internal pressure supported by the cylindrical cell. The signals recorded with the gauges glued on the cell give information on its response under concrete pressure.

The selected high strength concrete "MB50" has already been extensively studied [15-18]. The specimens to be tested were machined in a concrete block after being dried (40 days) to prevent the effects of drying shrinkage of the concrete. The composition and the mean mechanical properties of MB50 are detailed in Table 1.

TABLE 1. Composition and mechanical properties of MB50 concrete.

Composition of MB50 [15]	
Sand (kg/m ³)	1783
Cement (kg/m ³)	400
Water (kg/m ³)	200
Admixture (kg/m ³)	12
Water/Cement	0.5
Max grain size (mm)	5
Mechanical properties of MB50 [15]	
Compressive strength (MPa)	70
Tensile strength (MPa)	3.0

Methodology of processing of experimental data

First, it is studied how the pressure applied by the concrete to the inner surface of the cell is related to the hoop strain measured at its outer surface. To do so, numerical simulations of the cell loaded by an internal pressure were carried out using the finite elements computer code Abaqus-Standard [19]. A similar approach was successfully applied before to a smaller steel ring which elastic limit was lower [20]. The computations showed a noticeable barrelling of the cell. In the present case, the geometry of the cell is as described before (outer diameter equal to 65 mm, inner diameter equal to 30 mm and 45 mm height). Two numerical simulations were carried out to take account of the change in length of the specimen during the test. In both cases, a continuously increasing radial compressive stress is applied on the inner surface (cylindrical). In the first case, this pressure is applied to a central part of the cell 40mm long (smaller than the cell length), equal to the initial length of the sample. In the second numerical simulation, the pressure is applied to a shorter central part 34mm long (equal to the specimen length at the end of the test in the case of a nominal axial strain equal to -15%). The two curves (internal-radial-stress versus external-hoop-strain) are plotted in Figure 2. From both simulations, it is shown that the cell remains in the elastic range when the internal pressure is lower than approximately 300 MPa, and the external hoop strain is approximately lower than 0.1%. Anyway, the post-processing of the data proposed below that is based on the interpolation between above loadings is still possible when the cell is plastically loaded. In such a case, the same cell could not be used more than once. From curves of Figure 2, the relation between the measured outer hoop strain $\varepsilon_{\theta\theta}^{(z=0, ext)}$ and the radial inner stress $\bar{\sigma}_{radial}^{(int)}$ is built according to equation [1].

$$-\bar{\sigma}_{radial}^{(int)}(\bar{\varepsilon}_{axial}, \varepsilon_{\theta\theta}^{(z=0, ext)}) = \left(1 - \frac{\bar{\varepsilon}_{axial}}{\varepsilon_B}\right) \sigma_A(\varepsilon_{\theta\theta}^{(z=0, ext)}) + \left(\frac{\bar{\varepsilon}_{axial}}{\varepsilon_B}\right) \sigma_B(\varepsilon_{\theta\theta}^{(z=0, ext)}) \quad (1)$$

where σ_A and σ_B are the functions identified from Figure 2 and ε_B is a reference strain equal to 0.15. It will be assumed in the following that the radial stress is homogeneous in the sample and consequently is equal to the radial stress applied by the sample to the cell ($\bar{\sigma}_{radial}^{(int)} = \bar{\sigma}_{rr}^S$). Moreover, in the above simulations, the strains (and stresses) can be calculated at any point in the cell. Figure 2b shows the evolution of the inner hoop strain at points $z = 0$ (the axial symmetry plane) and $z = h_0/2$ (the initial specimen ends) for both simulated loading cases (A and B) as a function of the external hoop strain ($\varepsilon_{\theta\theta}^{(z=0, ext)}$). It appears (as expected) that the barrelling effect is stronger in the case B ($h_{press} = 34$ mm) than in the case A ($h_{press} = 40$ mm). It is then possible to compute the average inner hoop strain along the specimen height (between $z = 0$ to $z = h_{specimen}/2$) knowing the outer hoop strain measured on the cell and the axial strain of the specimen. Then, knowing the average radial strain of the specimen, the average specimen area is obtained:

$$\bar{A}_s = A_0(1 + f(\varepsilon_{\theta\theta}^{(z=0, ext)})), \quad (2)$$

The average axial stress is then:

$$\bar{\sigma}_{ZZ}^S = \frac{F_{axial}}{\bar{A}_s}, \quad (3)$$

where F_{axial} is the force deduced from SHPB measurements.

FIGURE 2a, left. Internal pressure versus external hoop strain ($z=0$)
 FIGURE 2b, right. Internal hoop strains ($z=0, h/2$) versus external hoop strain ($z=0$)

FIGURE 2. Numerical simulation of a cell internally loaded by a pressure applied to its central part (A: 40 mm, B: 34 mm).

The radial stress being known, the average deviatoric stress is:

$$\bar{\sigma}_{deviatoric}^S = \left| \bar{\sigma}_{zz}^S - \bar{\sigma}_{rr}^S \right|. \quad (4)$$

The average hydrostatic pressure and the volumetric strain are given by the formulas:

$$\bar{P}_{hydrostatic}^S = -\frac{1}{3} \left(\bar{\sigma}_{zz}^S + 2\bar{\sigma}_{rr}^S \right), \quad (5)$$

$$\bar{\epsilon}_{volumic}^S = (1 + \bar{\epsilon}_{axial}^S)(1 + \bar{\epsilon}_{rr}^S)^2 - 1. \quad (6)$$

Knowing the axial stress and the internal pressure, the deviatoric behaviour (i.e. the supposed evolution of the deviatoric stress versus the hydrostatic pressure) and spherical behaviour (variation of the volumetric strain versus the hydrostatic pressure) can be calculated.

Numerical validation of the method

In order to check the validity of the proposed method used to process the experimental data, artificial experimental tests are built with numerical simulations. These simulations use the concrete plasticity model (the KST model, see underneath). Meanwhile, the main hypothesis introduced in previous chapter will be justified (influence of the specimen shortening, of the cell inflation, homogeneity of the radial stress field).

The Krieg, Swenson and Taylor (KST) model

The model of Krieg, Swenson and Taylor [21, 22] is relatively simple and was implemented as a Fortran procedure (Vumat) in the Abaqus-Explicit code [23]. It describes the spherical behaviour by a compaction law linking the volumetric strain to the hydrostatic pressure (Table 2). The final constant compressibility modulus K_r (Table 2) is used for highest pressures ($P > 1$ GPa). Moreover, the Von Mises equivalent stress σ_{eq} cannot exceed a function of the hydrostatic pressure P (equation 7).

$$\sigma_{eq} = \min_P \left(\sqrt{a_0 + a_1 P + a_2 P^2}, \sigma_{mises}^{max} \right) \quad (7)$$

The coefficients (a_0 , a_1 , a_2) used in the subsequent simulations were identified from triaxial compression tests carried out under different confining pressures with MB50 concrete [18]. These coefficients are indicated in Table 2.

TABLE 2. Parameters of the Krieg, Swenson and Taylor model used in the numerical simulations

Density, elastic constants:	ρ, E, ν	2.386, 36 GPa, 0.2
First point of the compaction curve:	$\varepsilon_v^{(1)}, P^{(1)}$	-0.003, 60 MPa
Second point of the compaction curve:	$\varepsilon_v^{(2)}, P^{(2)}$	-0.2, 1 GPa
Initial and final bulk moduli:	K_i, K_f	20 GPa, 20 GPa
Coefficients of the elliptic equation:	a_0, a_1, a_2	1800 MPa ² , 240 MPa, 0.6
Maximum equivalent stress:	σ_{mises}^{max}	550 MPa

Numerical simulations of one 1D-strain compression test

Half of the cylindrical concrete specimen is compressed between a cylindrical steel compression plug and the axial symmetry plane ($z = 0$, Figure 3). An axial velocity is imposed on the upper surface of the compression plug. Under-integrated axisymmetric finite elements CAX4R are used. The numerical simulation of Figure 3 uses parameters illustrated in Table 2. Figures 3a and 3b show the iso-contours of the hoop and axial strains for a nominal axial strain nearly equal to -20%. One can notice the continuity of the hoop strain field between the sample and the cell. The axial strain and the stress fields are also almost homogeneous in the sample ($-1100 \text{ MPa} > \sigma_{zz} > -1400 \text{ MPa}$). A concentration of stresses is observed near the contact between the plug and the sample. It is due to the smaller diameter of the plug (Figure 3d). Moreover, it is observed that the radial stress is homogeneous in the sample and is constant at the contact between the plug and the sample (Figure 3c). This point justifies the assumptions used for the numerical simulations involving the cell only (Figure 2).

FIGURE 3. Numerical simulation of a 1D-strain compression test assuming a null friction.

Discussion and validation of the methodology of processing the data

Figures 4, 5, 6 and 7 correspond to the processing of numerical simulations. For each following graph, the curve that corresponds to the imposed material behaviours according to Table 2 is compared with the curve obtained with the method that will be used to process experimental data (equations [1, 2, 3]). The result of the processing of the numerical simulation of Figure 3 is shown on Figure 4. No difference is observed between the “KST” curve (imposed material behaviour) and the curve from the processing of data. This very good agreement proves the quality of the processing method when there is no friction (satisfactory interpolation taking account of the specimen length). On the opposite, worse comparisons that are seen in Figures 5 show the effect of neglecting the axial contraction of the sample in equation [1] (Fig. 5a), or its radial swelling to evaluate the axial stress in equation [2] (Fig. 5b) or neglecting again the radial swelling to compute the volumetric strain in equation [6] (Fig. 5c).

FIGURE 5. Illustration of possible uncompleted assumptions used in the processing of experimental data (based on the results of the numerical simulation of Figure 3)

Influence of the friction on the precision of the analysis

In the calculations leading to Figure 6, a coefficient of friction equal to 0.1 is used at the concrete sample/ring interface. The contact between the plug and the sample is assumed being without friction. In this case, one observes a maximum difference of deviatoric stress about 9% between the “KST” curve (imposed material behaviour) and the curve from the processing of data (Figure 6, left), which is definitely more important than without friction (Figure 4). It is also seen that the volumetric strain is underestimated at the end of the loading. Finally, the observed deviation on the volumetric strain is lower than approximately 5%, up to a pressure of 900 MPa (Figure 6, right). Figure 7 corresponds to the processing of a numerical simulation with a coefficient of friction equal to 0.1 at the concrete sample/plug interface. The contact between the ring and the sample is assumed being without friction. In that case, the deviation is seen to be as small as on Figure 4. Therefore, friction at sample/plug interface appears without any influence on the processing of data.

FIGURE 6. Processing of a numerical simulation of a test with friction between the specimen and the cell ($f = 0.1$)

FIGURE 7. Processing of a numerical simulation of a test with friction between the plug and the specimen ($f = 0.1$)

These numerical simulations allowed evaluating the quality and the robustness of the proposed processing method for 1D-strain compression tests. It appears necessary to take into account the plastic strain of the confining cell when the inner

pressure exceeds approximately 400 MPa. Moreover, as shown in the numerical simulations of the test, one also needs to take into account the sample shortening and its small radial expansion. The friction has a limited influence when the friction coefficient does not exceed 0.1. To conclude, according to these numerical simulations, the deviation from real values of the deviatoric stress and of the volumetric strain due to the method will remain lower than 9% and 5%, respectively.

Dynamic behaviour of MB50 concrete

Three dynamic 1D-strain compression tests were carried out with MB50 concrete samples (diameter: 30 mm, height: 40 mm) and with the confining cells described above. The assumption of a negligible friction between the cell and the specimen is specially addressed. The deviatoric behaviour (evolution of the deviatoric stress versus the hydrostatic pressure) and the spherical behaviour (evolution of the hydrostatic pressure versus volumetric strain) are computed.

Figure 8 shows the evolution of stresses and strains deduced from the processing of experimental data for one of the three 1D-strain compression tests. This test was carried out at a mean strain rate equal to 221 s^{-1} . The maximum value of strain rate reached during the test is equal to 415 s^{-1} . The maximum hoop strain G2 was 0.2%. Consequently, the cell had not a purely elastic behaviour, according to the numerical simulations of Figure 2. It is also observed that the loading can be divided into two phases (Figure 8a). Between 0 and 100 μs , the axial stress increases and the radial stress remains very low, like in a uniaxial compression test. Between 100 and 800 μs , the deviatoric stress and the hydrostatic pressure increase up to 1000 MPa and 900 MPa, respectively. The radial stress reaches 570 MPa at the end of the test. The axial strain reaches the minimum value of -19% . The inner radial strain remains very small (Figure 8b). Consequently this test was close to a 1D-strain compression test. The spherical and deviatoric behaviours corresponding to this test are shown on Figure 9 (curve " 221 s^{-1} ").

FIGURE 8a, left. Average stresses in the specimen (from processed data)

FIGURE 8b, right. Average strains in the specimen (from processed data)

FIGURE 8. Evolution of stresses and strains for a 1D-strain compression test performed at 221 s^{-1} .

FIGURE 9. Behaviour of MB50 concrete deduced from three 1D-strain compression tests.

The three 1D-strain compression tests show that the deviatoric and spherical behaviours appear almost independent of the strain rate in the (rather narrow) observed range of strain rates ($80\text{--}221\text{ s}^{-1}$, Figure 9). The deviatoric strength increases regularly with the hydrostatic pressure to reach 950 MPa under a pressure of 900 MPa (test " 221 s^{-1} "). Considering the spherical behaviour, an almost constant dynamic modulus of compressibility (around 5 to 6 GPa) is observed with the three 1D-strain compression tests up to a pressure of 900 MPa. It is smaller than the one deduced from purely hydrostatic compression tests (9 to 20 GPa) using a tri-axial cell (same concrete) [18] underlining a possible influence of the loading path or the strain rate on the response.

Conclusions

In this work, a testing device coupled to a new methodology of processing the experimental data were proposed allowing for the analysis of the mechanical behaviour of geomaterials under dynamic 1D-strain loading. This method leads to the knowledge of the deviatoric and spherical behaviours of the material tested. It is shown that as well the plastic behaviour of the cell as the shortening and the swelling of the specimen have to be taken into account in the analysis. Various numerical simulations of the test were carried out with the concrete plasticity model of Krieg, Swenson and Taylor. The method was applied successfully to artificial experimental data (free of noise) provided by those simulations. Moreover, a numerical simulation was carried out with a constant friction coefficient equal 0.1. It proves a weak influence of friction (between the cell and the sample) on the computed response of the concrete behaviour. Three 1D-strain compression tests were performed and analysed with the proposed methodology of processing. They show that a high level of compaction strain (20%) is available with this testing device. Stresses up to 1000 MPa, confinement pressures up to 600 MPa and a strain rate range between 100 and 500/s can be achieved to suitably provide data to evaluate the dynamic behaviour of concrete and other rock-like materials under multiaxial dynamic loadings.
