Light-induced piston nanoengines: ultrafast shuttling of a styryl dye inside cucurbit[7]uril†

Ekaterina Y. Chernikova,^a *^a Daria V. Berdnikova,^{ab} Yuri V. Fedorov,^a Olga A. Fedorova,^a François Maurel^c and Gediminas Jonusauskas^d

The combination of photoactive styryl(pyridinium) dyes and cucurbit[7]uril (CB[7]) in an integrated supramolecular system allowed us to design a novel high speed molecular machine based on the fully reversible shuttling motion of the dye inside the CB[7] host cavity. The driving force of this movement is the electrostatic potential change after the occurrence of intramolecular charge transfer in the excited state of the dye molecule that can be externally controlled by light. Steady-state and time-resolved optical spectroscopy as well as DFT calculations provided an unambiguous evidence for the ultrafast piston-like movement of the system between two states. The shuttling process occurs in the picosecond timescale and its bistability depends on the strength of the dye donor fragment.

The creation of artificial nanoscale machines, such as molecular rotary motors, muscles, and switches, that mimic actions of natural biofragments is a highly topical research area of modern supramolecular chemistry.¹⁻⁵ The ongoing interest in synthetic molecular machines not only arises from the desire to understand mechanisms of the formation and functioning of biological structures but is also supported by their potential applications in designing smart molecular devices, targeted drug delivery systems and various functional assemblies.

Molecular shuttles constructed from ring-shaped host molecules that encircle rod-like guest molecules due to non-covalent interactions and can reversibly switch the position between

two stable points sliding along the guest are of particular importance.⁶⁻¹⁰ Aiming for the construction of artificial molecular shuttles, we focused our attention on cucurbit[*n*]urils (CB[*n*]) as the preferred host molecules. In the majority of CB[*n*]-based systems, the control of the shuttling process is performed by various external stimuli such as changes in pH, redox states, and temperature.^{11,12} Surprisingly, the examples of light-responsive CB[*n*]-based shuttles are still rather rare, although the excited state properties of CB[*n*]-guest complexes upon light irradiation were a subject of extensive investigations.¹³⁻²¹ Thus, photoresponsive CB[*n*]-based shuttling systems operated by photochemical *E-Z*-isomerization of azobenzene derivatives^{22,23} or photoinduced electron transfer in pseudorotaxanes²⁴⁻²⁶ were reported. The reversibility of the latter systems, however, is usually achieved only in the presence of a photosensitizer or/and a sacrificial reductant.²⁴⁻²⁶

In this paper, we combine the knowledge in the field of CB[*n*]-based molecular shuttles and excited state properties to design the light-controlled systems where the shuttling process occurs without any chemical rearrangement and produces no waste. Herein we describe an elegantly simple approach towards the design of a high speed molecular shuttle based on photoactive molecules **1** and **2** and a macrocyclic CB[7] host (Chart 1). Notably, the switching is based on the photoinduced intramolecular charge transfer (ICT) process that is characteristic

of the highly polar π -conjugated D-A dye molecules.²⁷ Considering the affinity of CB[7] towards cationic species,^{28–30} we assumed that the photoinduced ICT-based displacement of the positive charge from the pyridinium ring to an oxygen (dye **1**) or nitrogen (dye **2**) atom of the aryl fragment will shift CB[7] along the dye from the pyridinium moiety towards the styryl fragment in the excited state. The *N*-methyl-4-styryl(pyridinium) dyes bearing O-donor (dye **1**) and N-donor (dye **2**) atoms were synthesized according to the published protocols.^{31,32} Derivatization with crown ether residues increases the solubility of the dyes in an aqueous medium. The binding properties of **1** and **2** with CB[7] in aqueous solution were the subject of our previous studies.^{33,34} UV-vis and NMR spectroscopy data confirmed the formation of the stable inclusion 1:1 complexes CB[7]-**1** and CB[7]-**2** driven by a hydrophobic effect and ion-dipole interactions with preferential immersion of the vinyl(pyridinium) unit of dyes **1** and **2** into the CB[7] cavity (Table 1). The identical complexation pattern resulted in the equal stability constant value of $\log K = 5.36 \pm 0.02$ for both dyes **1** and **2**.

It is well known that photophysical characteristics (*e.g.* emission spectra, fluorescence intensity and lifetimes) of chromophoric guest molecules are influenced by their positioning in the CB[7] host cavity.^{13,16,35–37} Since the binding site for CB[7] is the same in the host-guest complexes of CB[7] with dyes **1** and **2**, one can assume that the complexation-induced fluorescence changes should be similar in both cases. However, the experimentally observed fluorescence emission changes upon complexation of dyes **1** and **2** with CB[7] are specific for each dye (Table 1). Thus, the addition of CB[7] to the solution of **1** caused a moderate blue shift ($\Delta\lambda = 20$ nm) of the emission band along with a slight enhancement of the fluorescence quantum yield (*ca.* 1.2-fold).³³ In contrast, the binding of **2** to CB[7] resulted in a significant enhancement of the dye fluorescence (*ca.* 20-fold) with a less pronounced blue shift ($\Delta\lambda = 10$ nm) of the guest fluorescence maximum.

We used DFT calculations to analyze the evolution of charge distribution in free dyes **1** and **2** while going from the ground to the first excited state (Table S1, S2 and Fig. S3, S4, ESI[†]). It was clearly shown that in the ground state S_0 the positive charge in **1** and **2** is mainly localized on the pyridinium fragments. In the excited state S_1 of **1** and **2**, the charge transfer of 0.33 $|e|$ takes place from the phenyl ring to the pyridinium fragment, whereas the ethylene bridge keeps a constant charge value. Consequently, the electronic excitation to the first excited state leads to a decreasing positive charge on the pyridinium groups and an increasing positive charge on the dimethoxyphenyl (dye **1**) or

dimethylaminophenyl (dye **2**) moieties, which is anticipated for the ICT phenomenon. It is expected that such redistribution of charge will change the binding site for CB[7] that promotes the displacement of the excited dye molecule in the CB[7] cavity.

The formation of CB[7]-**1** and CB[7]-**2** inclusion complexes also was studied using DFT calculations. The large size of the cucurbituril host-guest complexes makes the quantum chemical investigation of the excited state computationally demanding. Therefore, to study the inclusion complex formation and locate possible minimum energy structures, we performed an energy scan calculation with both the isolated host and guest kept frozen at the optimized structure corresponding to the isolated molecules. Therefore, we calculated the evolution of the energy with respect to a scan coordinate (d) chosen as a distance between the carbon atom of the methyl group of **1** or **2** and a dummy atom located in the center of mass of the CB[7] cavity. A detailed description of the DFT calculations is given in the ESI.[†]

The obtained potential energy curves allowed the identification of one minimum energy structure for the complexation of dye **1** with CB[7] and two minimum energy structures with dye **2** (Fig. S5 and S6, ESI[†]). Notably, the inclusion of **1** or **2** in the CB[7] cavity occurs either barrierless or with just a very low energy barrier. For dye **1**, the inclusion process in CB[7] is associated with a strong decrease of the energy from the initial structure ($d = 0$ Å) to the minimum energy structure ($d = 4.2$ Å), in which the interaction energy ΔE_{int} is found to be -13.3 kcal mol⁻¹. The structure of the complex with the minimum energy shows that the pyridinium moiety of **1** is completely inside the CB[7] cavity and the electrostatic interaction between the pyridinium and the oxygen portal of CB[7] takes place. The presence of the only minimum on the potential energy curve does not support the formation of another stable configuration for the complex, therefore making bistable shuttling of dye **1** inside the CB[7] cavity questionable. At the same time, the inclusion process of **2** with CB[7] shows two minima, A and B (Fig. S6, ESI[†]), located at distances $d = 3.4$ Å and 6.2 Å, respectively. Minimum A is more stable than B by 10.9 kcal mol⁻¹ in the ground state S_0 and by 8.6 kcal mol⁻¹ in the first excited state S_1 . The interaction energy ΔE_{int} calculated in the lowest minimum A in the ground state is -9.8 kcal mol⁻¹. This value is somewhat greater than the interaction energy obtained in the CB[7]-**1** complex, indicating that under the conditions used for the calculations dye **2** is more weakly bound to CB[7] than **1**.

As it was mentioned above, the energy scan curves were obtained using a frozen geometry of the host and guest molecules. The geometries of inclusion complexes A and B were then fully optimized in the ground S_0 and excited S_1 states for the CB[7]-**2** complex. After optimization, complex A was found to be more stable than B by 0.8 kcal mol⁻¹ in the ground state while B is more stable than A by 2.9 kcal mol⁻¹ in the S_1 state. From the calculations, it can be, therefore, anticipated that the displacement of **2** in the cavity can be induced by electronic excitation from the position A ($d = 3.4$ Å) to B ($d = 6.2$ Å) leading to a total displacement of 2.8 Å as shown in Fig. 1. Eventually, it means that upon light excitation dye **2** moves inside the CB[7] cavity like a

Fig. 1 Schematic representation of potential energy curves of CB[7] 2 in the ground S_0 and excited S_1 states and illustration of the moving principle of the light induced molecular shuttle based on the ICT process.

piston in a cylinder. The reverse movement of CB[7] occurs spontaneously as soon as the dye molecule relaxes from the excited to the ground state.

Taking into account the results of DFT calculations, all further experimental studies were performed for the CB[7]-2 system. The processes occurring in the excited state of 2 were examined in detail. Thus, dye 2 possesses low fluorescence quantum yields ($\phi_f = 0.011$) in aqueous solution (Table 1) and is known to undergo very fast non-radiative relaxation of the excited state through the formation of a twisted intramolecular charge transfer (TICT) state in polar solvents.³² In the case of amino(styryl)pyridinium derivatives, three possibilities with different activation energies for rotating processes were reported.³⁸⁻⁴¹ Thus, for dye 2, the rotation about the aniline-ethylene bond should be the easiest one since it would have to possess the lowest energy barrier to rotation in the S_1 state. The rotation about the pyridyl-ethylene bond is also possible but not favored in solvents with high dielectric constants (e.g. water). Finally, the rotation of the crown-derived dimethyl-amino group should be the most hindered one due to the fragment bulkiness and, therefore, the highest potential barrier. Therefore, the rotation about the dimethylaminophenyl-ethylene single bond and the passage through the TICT state involving a “loose bolt” relaxation mechanism of the excited state revealed to be the main pathway for the non-radiative decay of dye 2 (see details in the ESI,† Section S7).³⁹⁻⁴¹ It should be noted that the high-energy barrier to rotation about the double bond in the S_1 state prevents the photoisomerization of dye 2 in most polar solvents.⁴²⁻⁴⁴

To determine the energy barrier for the non-radiative relaxation of dye 2 and complex CB[7]-2, temperature dependent studies of fluorescence quantum yields were performed using the modified Arrhenius equation (see details in the ESI,† Section S5).⁴²⁻⁴⁴ Thus, the activation energy values for 2 and CB[7]-2 have been estimated to be $\Delta E_a = 3.9 \pm 0.3 \text{ kcal mol}^{-1}$ ($16.2 \pm 1.1 \text{ kJ mol}^{-1}$) and $\Delta E_a = 3.8 \pm 0.2 \text{ kcal mol}^{-1}$ ($15.9 \pm 0.6 \text{ kJ mol}^{-1}$), respectively. It can be seen that the activation barriers for the non-radiative deactivation process in the excited state of dye 2 and complex CB[7]-2 are close to each other and also to the activation energy of the viscous flow for

pure water, 15.9 kJ mol^{-1} .⁴⁵ In other words, in water the TICT process occurs without any barrier in both free dye 2 and its complex CB[7]-2. Nevertheless, it was found that the Arrhenius pre-exponential factor decreases by two orders of magnitude upon complexation from 1.1×10^{13} to 2.2×10^{11} . According to the theory of the activated complex for unimolecular reactions,⁴⁶ the decrease of the Arrhenius pre-exponential factor indicates that the probability of the TICT state formation for complex CB[7]-2 is lower than that for free dye 2. From the physical point of view, it can be explained by the decrease of the number of efficient collisions of 2 with water molecules leading to the twisting of 2. Eventually, it means that in the excited state of the complex CB[7] is shifted towards the phenyl ring, thus shielding the aniline-ethylene bond from the polar solvent and hindering its twisting. The importance of changes of the pre-exponential factor on reaction kinetics has previously been found for various compounds.^{38,47}

To characterize the dynamics of the excited state relaxation and provide further insight into the light-induced movement of the dye 2 molecule inside the CB[7] cavity, the femtosecond transient absorption spectroscopy (TRABS) was applied (see details in the ESI,† Section S6).⁴⁸ A characteristic result of a pump-probe TRABS experiment for 2, i.e. a map of absorbance changes after light excitation in delay-wavelength coordinates, is displayed in Fig. 2a. Here, two essential features can be clearly observed. Firstly, there is a positive band at about 520 nm corresponding to the excited state absorption (ESA), which appears together with the pump pulse. Most importantly, one may note a stimulated emission (SE) band in the wavelength region of 560-660 nm, which is associated with the fluorescence of dye 2. The maximum of the SE band undergoes a noticeable red shift with increasing time delay. The changes of the SE band position during the first few picoseconds represent the dynamic solvation that is environment (solvent) reorganisation around the dye molecules. The dynamic solvation is a result of the dye dipole moment change after the ICT process occurred upon excitation. The reorganisation of the dye environment lowers the potential energy of the solute-solvent system in the excited state and, therefore, induces the red shift of the SE band.

A graphical representation of the SE band maximum displacement with time for free dye 2 is illustrated in Fig. 2b and Fig. S13a, ESI.† In general, the solvation dynamics in water is

Fig. 2 (a) TRABS map for dye 2 in H_2O measured upon 470 nm laser excitation in the 490-780 nm spectral range and (b) the kinetic traces of the stimulated emission displacement during first several picoseconds for dye 2 (black circles) and its complex CB[7] 2 (blue squares), measured using the femtosecond time resolved pump-probe technique.

Fig. 3 Electrostatic potential surface of: (a) CB[7] (top and side views), (b) dye **2** in the ground state and (c) dye **2** in the excited S_1 state.

non-monoexponential and includes at least three components: 0.1 ps (inertial motion), 0.3–0.7 ps and 1.4–3.5 ps for dyes of different natures (cationic, anionic and neutral).^{49–51} The average solvation time constant for all the dyes studied in the work⁵¹ was in the range of 0.43–0.48 ps and was almost independent of the nature of the solute. We fitted the corresponding kinetic decay curve (black circles) to a biexponential function by using 0.34 ps (dominant contribution) and 0.97 ps time constants. The first time constant represents the average between the inertial motion of water and the first rotational movement of the water molecule. The second time constant in our fit corresponds to the third time constant discussed above.

As soon as dye **2** was confined in the CB[7] cavity, no time constant of 0.34 ps corresponding to the solvation in water was found. The displacement of the SE band in this case is slower with the time constant of approximately 0.57 ps (Fig. 2b, blue squares, and Fig. S13b, S14, ESI[†]). Since CB[7] acts like a new environment for the dye molecules, the displacement of the SE band represents now the rearrangement of the CB[7]–**2** system in the excited state in order to lower the overall potential energy of the system.

We attribute the time constant of 0.57 ps to the movement of the guest in the cavity of the host because upon excitation a new positive charge distribution should be followed by the reaction of the negatively charged inner rims of CB[7] (Fig. 3). This means that the electrostatic attraction is weakened on the side of the pyridinium subunit of the dye in the excited state due to the positive charge transfer towards the phenyl subunit. As shown in Fig. S4 (ESI[†]), the positive charge drops from 0.84 to 0.49 on the pyridinium when going from the ground state to the excited state for dye **2**. An increase of the positive charge on the phenyl subunit (from 0.22 to 0.59) now exerts a much stronger attraction of the closer CB[7] rim than that in the ground state. This must be followed by the movement of the relatively rigid cucurbituril molecule in order to adapt the position of negatively charged oxygen rims with respect to the new distribution of positive charges and thus reduce the potential energy of the complex.

The fluorescence data also support the hypothesis that the emission takes place from such a complex geometry where CB[7] is located on the dimethylaminophenyl fragment of dye **2**.

We, therefore, deduced that the time constant obtained from kinetics analysis as 0.57 ps for the CB[7]–**2** complex can be reliably assigned to the dye molecule movement time inside the CB[7] cavity.

Proceeding from the solvation time constant and the estimated distance separating two binding sites of CB[7] (2.8 Å from the DFT calculations) in the ground and excited states we deduced the average rate of the movement of dye **2** versus CB[7]. Thus, the displacement rate for dye **2** in the CB[7] cavity is 0.49 nm ps⁻¹ (490 m s⁻¹). As soon as the excited state of the dye is relaxed, the ground state charge distribution is restored, which causes the backward movement of the dye molecule inside the cavity until the initial CB[7] binding site is reached. Evidently, this light-driven shuttling process is fully reversible and can be repeated over many cycles.

From the above analysis we finally conclude that the light-induced movement in the CB[7]–**2** system is the ultrafast process and it clearly not only depends on the thermodynamic parameters but also – and, probably, principally – is driven by the electrostatic force arising from the dipole moment change in the excited state of the encapsulated dye. The strength of the donor substituent in the phenyl ring of the dye is a crucial factor influencing the dye moving inside the CB[7] cavity. It should be also noted that the operation rate of our light-induced molecular shuttle (0.57 ps for forward movement) is faster than those of the earlier described pseudorotaxane systems by four-to-six orders of magnitude (1–100 μs for forward movement).^{52,53}

Conclusions

To sum up, we have constructed an ultrafast piston nanoengine based on the light-induced movement of styryl(pyridinium) dye **2** inside the CB[7] cavity. The driving force of the movement is the ICT process occurring in the dye molecule upon photoexcitation. The shuttling motion of the system between two states is controlled solely by the light stimulus and is fully reversible. Bistability of the present system is achieved through different binding sites for CB[7] in the ground and excited states of the CB[7]–**2** complex. The described moving principle may be used for the creation of advanced molecular machines and devices possessing ultrahigh rates or for nanoflappers in drug delivery and release systems. To further develop this idea, structural variations of the photoactive constituent, namely, lengthening of the linker between the pyridinium and crown ether moieties or changing the strength of the donor/acceptor groups will be applied to create systems with tunable moving time parameters.
