III-nitride-on-silicon L3 photonic crystal cavities with resonances down to 315 nm and quality factors (Q) up to 1085 at 337 nm have been demonstrated. The reduction of quality factor with decreasing wavelength is investigated. Besides the QW absorption below 340 nm a noteworthy contribution is attributed to the residual absorption present in thin AlN layers grown on silicon, as measured by spectroscopic ellipsometry. This residual absorption ultimately limits the Q factor to around 2000 at 300 nm when no active layer is present.

Group-III-nitride nanophotonics is a booming field with demonstrations and potential applications ranging from the near-IR to the UV-A spectral range1–3. There have been several reports on III-nitride-based 1D and 2D photonic crystal (PhC) cavities in the IR3–5 and blue6–10 spectral ranges with large quality (Q) factors, using silicon (Si), sapphire, or silicon carbide (SiC) substrates. Fewer reports and with much lower Q factors have been made in the UV10–13, as the processing and the material growth are far more challenging. Q factors around 5000 have been achieved in the blue to UV-A range at 420 nm and 380 nm using 2D L7 cavities6 and 1D nanobeam cavities14,15, respectively. Optically pumped lasing has been achieved in L3 and H2 cavities around 370 nm with Q factors up to 170016. When going to shorter wavelengths (< 350 nm) much lower Q factors (< 1000) are observed for PhCs14. So far there have not been any good explanations for this phenomenon.

In previous work, we demonstrated Q factors of 80000 for microdisks with bus waveguides in the near-infrared17. The quality factor of the microdisks decreases when going to very short wavelength with Q factors exceeding 1000 in the range between 275 nm and 470 nm18. The same trend was observed with photonic crystals with Q factors going from 30000–40000 at telecom wavelengths19–21 down to 4000–5000 at 380 nm12–15. One open question is thus what happens at very short wavelength.

In this work, we demonstrate resonances down to 315 nm and Q factors up to 1085 at 337 nm for L3 two-dimensional photonic crystal cavities. Using spectroscopic ellipsometry, we determine residual absorption in AlN grown on Si. This residual absorption is expected to be the main cause of substantially decreased Q factors at shorter wavelengths when no active layers with a large absorption (quantum wells or quantum dots) are present. The investigated sample for photonic crystals was grown by ammonia molecular beam epitaxy (MBE) on standard Si (111) substrate. It consists of a 50 nm AlN buffer layer and 5 GaN (1.2 nm)/ AlN (5 nm) quantum wells (QWs) emitting at a wavelength of 310 nm. The heterostructure is depicted in figure 1(a).

**FIG. 1.** (a) Layer stack of the investigated sample grown on Si. (b) SEM image of a typical L3 cavity. The period a is 130 nm, the nominal r/a is 0.28, and the lateral holes of the L3 cavity are displaced by 0.10a.

Standard cleanroom processing is used to fabricate triangular lattice L3 photonic crystal cavities. Electron beam lithography (EBL), reactive ion etching (RIE), and inductively coupled plasma (ICP) utilizing Cl2 and BCl3 gases are used. A SiO2 hard mask is used to transfer the pattern from the resist into the III-N layer. Diluted ZEP resist is used for the EBL and hardened after development by electron irradiation with a scanning electron microscope (SEM) (dose 65 C/m²) for higher quality RIE of the SiO2 mask. The Si substrate is then underetched using XeF2 gas, resulting in suspended air hole membranes. A scanning electron microscope (SEM) image

Q factor limitation at short wavelength (around 300 nm) in III-nitride-on-silicon photonic crystal cavities

We have investigated L3 cavities with periods $a = 130$ and 120 nm and a nominal radius over period ratio $r/a$ of 0.28 to 0.31. The L3 cavities correspond to the design introduced by Akahane et al., i.e. of type 0, which means the two holes adjacent to the line defect are displaced, in our case by $d/a = 0.15$ to 0.25. Finite difference in time domain (FDTD) simulations show Q factors in the range of 1600 to 5000 for the L3 cavities. Larger Q factors can be achieved for smaller $r/a$. Using $d/a = 0.25$ and $r/a = 0.22$ for these L3 cavities would result in a large theoretical Q factor of more than 10000, however, such cavities are much harder to fabricate due to the much decreased hole sizes. Some theoretical papers are suggesting hole optimization schemes for L-type cavities, reaching Qs of $1 - 2 \times 10^6$. 

The PhC cavities are investigated using microphotoluminescence ($\mu$PL) at room temperature. A frequency doubled laser emitting at 244 nm is used as a pump. A microscope objective is used to focus the laser beam onto the PhC and to collect the emitted light, which is subsequently focused into the spectrometer slit with a lens and measured with a liquid nitrogen cooled charged coupled device (CCD).

Figure 2(a) shows typical $\mu$PL measurements for L3 cavities with a period of 130 nm. The broad emission, centered around 310 nm, comes from the QWs. The long wavelength resonances between 330 and 340 nm are the fundamental modes of the L3 cavity and the shorter wavelength peaks between 320 and 330 nm are the first-order modes. Shorter-wavelength modes cannot be seen because they are absorbed by the QWs. In figure 2(b) the Q factors of the fundamental modes shown in figure 2(a) are plotted over the wavelength. With increasing $r/a$ a blue shift and decrease in Q factor are observed, which matches well with FDTD simulations. The zoom-in of the spectrum and Lorentzian fit of the fundamental mode of the L3 cavity with $r/a = 0.28$ from figure 2(a) is shown in figure 2(c). The FWHM is $\Delta \lambda = 0.31$ nm and the Q factor is $Q = 1085$ at $\lambda = 337$ nm, which is the highest we obtained. FDTD simulations of the Hz field of the fundamental (top) and first-order (bottom) modes for $r/a = 0.28$ are shown in figure 2(d).
Q factor limitation at short wavelength (around 300 nm) in III-nitride-on-silicon photonic crystal cavities

classification of similar modes is reported by Chalcraft et al.\textsuperscript{24}.

FIG. 3. The dots are measured Q factors of fundamental modes of various L3 cavities with varying $a$, $r/a$, and $d/a$. The lines take both the QW absorption and the residual absorption of AlN into account and are fitted using two different values of $Q_{\text{design}}$, i.e. 1600 and 5000.

Going to shorter wavelengths reduces the Q factor, as can be seen in figure 3 and is also observed by Sergent et al.\textsuperscript{14} and Rousseau et al.\textsuperscript{8}. So far this phenomenon is rather unclear. Sidewall tapering, dispersion of holes, and surface and sidewall roughness have been suggested as the underlying cause\textsuperscript{8,14}. Another factor that contributes to the reduction in Q factor is the residual absorption of AlN grown on Si. The absorption could be caused by point defects such as Al vacancies (center energy at 3.6 eV) in the AlN-Si interface region, which are known to be absorption centers in bulk AlN\textsuperscript{25–27}. To confirm this hypothesis, we investigated several samples with varying AlN thicknesses between 50 and 100 nm on Si (111) by spectroscopic ellipsometry (SE)\textsuperscript{28}. In the model we use a two-layer stack consisting of an optically unknown Cauchy film (AlN) on top of a silicon substrate for which we use literature $n$ and $k$ values, which take the substrate absorption into account. Using the Cauchy formulas we determined $n$ and $k$ for the AlN layers.

$$n = A + \frac{B}{\lambda^2} + \frac{C}{\lambda^4}, \quad (1)$$

$$k = \alpha \exp \beta(12400(\frac{1}{\lambda} - \frac{1}{\gamma})), \quad (2)$$

with $A$, $B$, $C$, $\alpha$, $\beta$ being fit parameters\textsuperscript{29}. The fits were performed by taking $n$ from the Cauchy model of the sample with 50 nm AlN and determining $k$ by fitting the ellipsometry data of each sample to the Cauchy model ($n$ and $\beta$ constant for all samples). Figure 4 shows SE measurements (squares), highlighting the standard phase difference $\Psi$ and the amplitude ratio $\Delta$, and a Cauchy fit model (lines) for a sample with 80 nm AlN for angles of incidence of 65$^\circ$, 70$^\circ$ and 75$^\circ$. The set of Cauchy parameters that gives a good fit of $\Psi$ and $\Delta$ is not unique, resulting in small variations of $n$ and $k$. The inset in figure 4 shows the absorption coefficient $\alpha$ for the samples with different AlN thickness and a sample with a thin QW, where the AlN buffer layer was grown under different conditions (lower ammonia). The absorption coefficient $\alpha$ was determined using

$$\alpha_{\text{AlN}} = \frac{4\pi k}{\lambda}. \quad (3)$$

The trend first shows a systematic increase of absorption when going to shorter wavelengths. It also shows an increase in absorption with a decrease in thickness. However, the sample with the thin QW and the lower ammonia shows a higher absorption, although the QW absorption is outside of the depicted range at around 280 nm. Presumably the material absorption is strongly dependent on the growth parameters and ammonia flux.

The full lines in figure 3 show the fit model of the total Q factor of the PhC sample determined by

$$\frac{1}{Q_{\text{tot}}} = \frac{1}{Q_{\text{abs,QW}}} + \frac{1}{Q_{\text{abs,AlN}}} + \frac{1}{Q_{\text{design}}}, \quad (4)$$

where $Q_{\text{abs,AlN}}$ is given by

$$Q_{\text{abs,AlN}} = \frac{2\pi n}{\alpha \lambda}, \quad (5)$$

and is determined using $\alpha$ from the 80 nm AlN sample.
The 5 QWs contribute to the absorption that limits the Q factor. We approximate the QW absorption as \(Q_{abs,QW} = 3000 \text{ cm}^{-1}\) below 310 nm using

\[
o_{QW} \times L \approx \frac{\pi e^2}{2h} \times \Gamma = 6 \times 10^{-3} \times \Gamma,
\]

with the thickness of the QW \(L = 1.2 \text{ nm}\), the overlap factor between the 5 QWs and the mode \(\Gamma \approx 0.06\), the fundamental charge \(e\), and Planck’s constant \(\hbar\). We assume a linear decrease of \(\alpha\) down to 0 cm\(^{-1}\) at 340 nm, close to the PL cut-off. We consider two values of \(\alpha\) close to the PL cut-off.

The results in the inset of figure 4 indicate a reduction in absorption with increasing AlN thickness, which may be related to the material quality improving during the longer growth. Moreover in a thicker AlN layer the mode at 340 nm is limited experimentally to around 1000. Results indicate that achieving high \(Q\) factors at short wavelengths down to the UV-C is extremely challenging for very thin AlN layers (<100 nm) grown on silicon.

In conclusion, we have demonstrated high \(Q\) factor resonances in the UV-A with L3 photonic crystal cavities fabricated on a III-nitride-on-silicon sample. The \(Q\) factor at 340 nm is limited experimentally to around 1000. Residual absorption in AlN grown on Si is a significant limiting factor when no active layers are present. Our results indicate that achieving high \(Q\) factors at short wavelengths down to the UV-C is extremely challenging for very thin AlN layers (<100 nm) grown on silicon and would require specific optimization of the material growth.
