Impact of unresolved smaller scales on the scalar dissipation rate in direct numerical simulations of wall bounded flows

Cédric Flageul, Iztok Tiselj

Reactor Engineering Division, Jožef Stefan Institut, Ljubljana, Slovenia

Abstract

Passive scalar dynamics in a turbulent channel flow is studied with Direct Numerical Simulation at friction Reynolds number $Re_\tau = 160$ and Prandtl number $Pr = 1$. The goal of the study is to assess the grid spacing requirement for an accurate estimation of various integral turbulent statistics, with a special focus on the scalar dissipation rate. The implemented spatial resolutions span from the resolution comparable to the similar Direct Numerical Simulations (DNS) studies in the past, to the very fine resolution implemented by Galantucci and Quadrio [1]. All scalar fields are computed in parallel using a single velocity field resolved with the finest resolution, thus reducing the statistical variability. In addition, to confidently assess the grid spacing requirement, we also evaluate the statistical uncertainty. The “standard” resolution of the DNS studies (resolution used by Kim et al. [2]) is usually sufficient for predictions of first and second-order integral turbulence scalar field statistics. Non-negligible corrections of the fourth-order integral statistics, especially the scalar dissipation variance profile, are observed with enhancement of the scalar resolution from the one used in the “standard” DNS studies to the resolution recommended by Vreman and Kuerten [3], which is roughly two times finer in each spatial direction. Further resolution enhancements produce only marginal differences.

Keywords: Passive scalar, Dissipation rate, Anisotropy, Direct Numerical Simulation, Channel flow, Sampling error

1. Introduction

Since the pioneering efforts of Obukhov [4], Corrsin [5] and Batchelor et al. ([6, 7]), passive scalars in turbulent flows have been the focus of a number of studies. As summarized in the review by Warhaft [8], experiments and simulations are challenging classical descriptions of passive scalars derived from the Kolmogorov cascade phenomenology. Evidences suggest a strong coupling between large and small scales and no local isotropy at inertial and dissipation scales. They also suggest that passive scalars are associated with a stronger intermittency compared with the velocity.

Following Batchelor et al. ([6, 7]), for a unit Prandtl number as herein, the smallest spatial scale for scalar mixing is the Kolmogorov scale $\eta = (\nu^3/\bar{\varepsilon})^{1/4}$, where ν is the dynamic viscosity and $\bar{\varepsilon}$ the mean dissipation rate of the turbulent kinetic energy. Similarly, the smallest time scale is the Kolmogorov time scale $\tau_\eta = \sqrt{\nu/\bar{\varepsilon}}$. As the passive scalar is intermittent, locally, structures with a spatial (temporal) span shorter than η (τ_η) appear in a flow. Suspecting those fine structures to be related to highly dissipative events, a number of DNS have been performed with sub-Kolmogorov scales resolved (Schumacher et al. [9], Donzis and Yeung [10], Galantucci and Quadrio [1]).

One of the central quantity in those studies is ε_θ , the scalar dissipation rate, defined by

$$\varepsilon_\theta = 2\alpha|\nabla\theta|^2 = 2\alpha \left[\sum_{i=1}^3 (\partial_i\theta)^2 \right] \quad (1)$$

where α is the thermal diffusivity. According to Pope [11], this quantity he calls the all-important dissipation rate matters in combustion models. It is also a central quantity in Reynolds Averaged Navier-Stokes (RANS) turbulence models as it appears in the budget equation of the scalar variance. Lately, Flageul et al. [12] showed that the dissipation rate associated with the temperature variance is discontinuous at the fluid-solid interface in case of conjugate heat transfer. This is prominent for industrial applications where thermal fatigue is a concern.

Studying homogeneous isotropic turbulence, Schumacher et al. [9] showed that the improved resolution matters when investigating the tails of the Probability Density Function (PDF) of ε_θ , which correspond to low probability events associated with high or low dissipation rates. More specifically, they show that a poorer resolution has a stronger impact on regions of low ε_θ than on those of high ε_θ . On a similar configuration, Donzis and Yeung [10] showed accurate estimation of advanced statistics (scalar dissipation intermittency exponent, structure functions at moderately high orders and PDF of ε_θ up to $200 \overline{\varepsilon_\theta}$) with a grid spacing equal to the Batchelor scale, which is exactly the Kolmogorov scale in the present study.

Studying a turbulent channel flow ($Re_\tau = 160$, $Pr = 1$), Galantucci and Quadrio [1] extended the analysis to wall-bounded flows. They showed resolution effects on the profiles of the mean ε_θ and its variance, but also on the PDF of ε_θ and recommended a very fine spatial resolution ($\Delta_x^+ = \Delta_z^+ = 1$ and $0.43 < \Delta_y^+ < 2$). In the streamwise (spanwise) direction, this is 6 (4) times finer than what is necessary for the velocity according to Vreman and Kuerten [3]. The authors of the present study estimate that the resolution proposed by Vreman and Kuerten is sufficient for accurate predictions of the key integral turbulent statistics of the passive scalar field at $Pr = 1$, including the average scalar dissipation rate and its variance. **The main objective of the present paper is to assess this claim.**

The structure of the paper is as follows. In the second section, the governing equations and the computational setup are described alongside with the procedure to estimate the sampling error. In the third section, preliminary investigation on coarser grids is presented. In the fourth section, the DNS results are presented. Discussion and conclusions are collected in the last section.

2. Governing equations, computational setup and sampling error

Dimensionless equations of the incompressible turbulent channel flow with transport of a passive scalar can be found in various sources (Kasagi et al. [13],

Kawamura et al. [14]):

$$\nabla \cdot u = 0 \quad (2)$$

$$\partial_t u = -\nabla \cdot (u \cdot u) + \frac{1}{Re_\tau} \nabla^2 u - \nabla(p) + \vec{1}_x \quad (3)$$

$$\partial_t \theta = -\nabla \cdot (u \cdot \theta) + \frac{1}{Re_\tau Pr} \nabla^2 \theta \quad (4)$$

Equations (3) and (4) are normalized with the channel half width h , the kinematic viscosity ν and the friction velocity u_τ . Low friction Reynolds number $Re_\tau = 160$ and Prandtl number $Pr = 1$ were selected in order to replicate the conditions of the simulations performed by Galantucci and Quadrio [1]. As the
60 Prandtl number is unity, Kolmogorov and Batchelor length-scales are identical.

Periodic boundary conditions are used in the streamwise and spanwise directions, labelled x and z , respectively, while the wall-normal direction is labelled y . The forcing term $\vec{1}_x$ represents a constant pressure gradient in the streamwise
65 direction and has a unit amplitude thanks to the normalization used. Boundary conditions for the passive scalar fields at the channel walls are $\theta = 1$ at $y = 1$, and $\theta = -1$ at $y = -1$ and were previously used in the simulations of Papavassiliou and Hanratty [15], Johansson and Wikström [16], and Galantucci and Quadrio [1].

70 The equations are solved with a pseudo-spectral scheme. Fourier series are used in the x and z directions and Chebyshev polynomials are used in the y direction. Second-order accurate time differencing (Crank-Nicolson scheme for diffusive terms and Adams-Bashforth scheme for other terms) is used with maximum Courant number kept at approximately 0.1. The aliasing error is
75 removed with computation of the nonlinear terms on a grid 1.5 times finer in all directions. The computer code is based on the code developed by Gavrilakis et al. [17], which was later modified by Lam and Banerjee [18]. The code was used and verified in simulations of Tiselj et al. ([19], [20], [21]).

The extension of the computational domain, normalized with the channel
80 half width h , was taken from the work of Galantucci and Quadrio [1]: $L_x = 4.19$,

Scalar field	$Nx * Ny * Nz$	Δ_x^+	$[\Delta_{y,min}^+, \Delta_{y,max}^+]$	Δ_z^+
1KMM	40 * 129 * 60	16.8	[0.048, 3.93]	5.57
2GQC	64 * 129 * 64	10.5	[0.048, 3.93]	5.23
3S	112 * 129 * 80	5.99	[0.048, 3.93]	4.18
4VK	112 * 181 * 80	5.99	[0.024, 2.78]	4.18
5GQM	360 * 129 * 180	1.86	[0.048, 3.93]	1.86
6S	360 * 181 * 180	1.86	[0.024, 2.78]	1.86

Table 1: Spatial resolution for the transported passive scalar fields.

$L_y = 2$, and $L_z = 2.09$. Both in the streamwise and spanwise directions, this is about 3 times smaller than the domain used in Kasagi et al. [13]. Such a small computational domain neglects an important part of the large scale structures in the turbulent flow, however, it is known to be sufficient for special studies focused on small scale turbulent structures of the velocity field (Jimenez and Moin [22]). The small domain offers a platform for simplified studies of the resolution requirements. It is often overlooked that in addition to obliterating large scale structures, small domain can be affected by a significant sampling error. For instance, Galantucci and Quadrio [1] report up to 5% differences in the friction temperature values in their simulations performed on different resolutions and averaged over the time interval of 2400 viscous time units (statistics based on 60 instantaneous fields).

In the present study, the resolution requirement for the passive scalar field is examined with a single DNS run. The velocity field is calculated on the finest grid of $Nx * Ny * Nz = 360 * 181 * 180$ modes (Case 6S in Table 1). Six distinct passive scalar fields are simultaneously transported by this velocity field and resolved with different number of modes, see Table 1. The naming scheme for the passive scalar fields is inspired by the name of the authors who promoted certain resolution. For instance, in 1KMM, KMM stands for Kim, Moser and Moin [2]. Similarly, in 4VK, VK stands for Vreman and Kuerten [3]. The number preceding the letters corresponds to a disputable ranking of the grids:

1 for the coarsest, 6 for the finest. For the five scalar fields resolved with a lower resolution, all Fourier and Chebyshev modes above the indicated resolution are set to zero at the end of each time step.

105 This approach, which is comparable to the one in Brethouwer et al. [23] or Gotoh et al. [24], reduces the statistical variability and eases the separation of the sampling error from the error induced by a coarser spatial resolution. The separation of statistical uncertainty and resolution effects is of particular importance for the present work: the smaller extension of the domain in the
110 homogeneous directions increases the sampling error, which easily exceeds the tiny differences induced by the variable resolution of the passive scalar field, except for simulations with a very long duration.

The finer resolution (case 6S in Table 1) used in the wall-normal direction follows Vreman and Kuerten [3]. In the streamwise and spanwise directions, case
115 6S corresponds to the resolution used by Galantucci and Quadrio [1] in their “Medium” simulation. This is 2 to 3 times finer than the recommendation of Vreman and Kuerten [3]. Cases 5GQM and 2GQC correspond to the “Medium” and “Coarse” cases in Galantucci and Quadrio [1], respectively. The case 4VK is using the resolution recommended by Vreman and Kuerten [3]. The case
120 3S is similar to 4VK except that it uses a coarser wall-normal grid. Lastly, the resolution in case 1KMM is comparable with most of the previous DNS simulations (Kim et. al. [2], Kasagi et al. [13], Tiselj et al. [19]).

The present DNS is performed with a time step of $0.008 \nu/u_\tau^2$ and one snapshot is taken every 1000 time steps. 700 snapshots are used to reconstruct
125 the statistics, corresponding to an averaging time of $5600 \nu/u_\tau^2$.

DNS is widely used to produce reference data. However, as pointed out by Oliver et al. [25], statistics obtained from DNS contain non-trivial errors. Errors arise mainly from the discretization of the equations and from the finite statistical sampling. As our code is based on a pseudo-spectral method and we
130 use a fine grid, the spatial discretization error of the Navier-Stokes equation is rather low. Thus, the main source of error in our statistics is the sampling error, which we estimate with the open-source library `ar` (<https://github>.

com/RhysU/ar, see Oliver et al. [25]).

The program **arsel**, which ships with the library, is used as follows. For each
 135 statistical quantity of interest, the instantaneous value is extracted from each
 snapshot and averaged in the homogeneous directions. The resulting time series
 are used to fit autoregressive models with **arsel** using the `--subtract-mean`
 option. The output of **arsel** is then processed to extract the average profile
 and the sampling error profile. Herein, the sampling error is given as 2 standard
 140 deviations. Given the domain extension, the number of modes used and the time
 step, the probability that the real average and its estimation differ for less than
 2 standard deviations is 95%.

As this method can be applied for any statistical quantity, we are able to
 estimate the sampling error for the mean temperature, the temperature dissipa-
 tion rate or its variance. For a given variable ϕ , the associated sampling error
 is e_ϕ . We also define the dimensionless normalized sampling error $E[\phi]$ by

$$E[\phi](y) = \frac{e_\phi(y)}{e_\phi(y) + \text{abs}\left(\overline{\phi(y)}\right)} \quad (5)$$

This normalized sampling error is bounded in $[0, 1]$, the upper bound being
 reached when the averaged value $\text{abs}\left(\overline{\phi(y)}\right)$ is exactly zero. As most of the
 145 time the averaged value is large compared to the sampling error, $E[\phi]$ measures
 the relative uncertainty.

3. Preliminary results on coarser grids

The sampling error on u_τ^2 , whose theoretical value is 1 herein, and $\partial_y \bar{\theta}(y = \pm 1)$
 is illustrated with the four DNS studies on coarser grids described in the Table
 150 2. The results in the large computational box combined with the long and short
 averaging time are taken from the analyses of Tiselj and Cizelj [20], which were
 performed at $Re_\tau = 180$, $Pr = 1$ and with slightly different thermal boundary
 conditions: both channel walls were heated and a forcing term was present in the
 passive scalar equation (4). The small box results are part of the present anal-
 155 ysis: a separate run over longer time interval was made only with a resolution,

Label	Re_τ	L_x^+ L_y^+ L_z^+	Δ_x^+ $\Delta_{y,max}^+$ Δ_z^+	Averaging time in wall units	$u_\tau^2 \pm e_{u_\tau^2}$	$\partial_y \bar{\theta} \pm e_{\partial_y \bar{\theta}}$
18L	180	6786	17.7	24 300 (450 samples)	1.0004 ± 0.0016	-180.11 ± 0.15
18S		360 2262	4.42 5.89	5400 (100 samples)	0.9998 ± 0.0016 0.9997 ± 0.0029 1.0005 ± 0.0033	180.01 ± 0.14 -179.74 ± 0.29 180.14 ± 0.46
16L	160	670	16.8	24 000 (500 samples)	1.002 ± 0.014	6.80 ± 0.05
16S		320 334	3.93 5.57	6000 (125 samples)	1.003 ± 0.019 1.005 ± 0.026 0.990 ± 0.050	6.78 ± 0.08 6.82 ± 0.10 6.63 ± 0.24

Table 2: Sampling error on friction velocity and temperature derivative at the boundaries.

which corresponds to the case 1KMM in Table 1.

The first impression about the statistical uncertainty can be obtained from the two **rightmost** columns of Table 2 where the squared friction velocities and temperature derivatives at both channel walls are shown. As one might expect, deviation from the theoretical friction velocity of 1 is larger in the smaller computational domain and at shorter averaging time intervals. As for the temperature derivative, shorter averaging time also leads to higher sampling error. Regarding cases $Re_\tau = 160$, we observe a relatively large difference on the temperature derivative at both walls. Although this difference gets lower when increasing the duration of the simulation, it is probably specific to smaller computational domains, as reported by Jimenez and Moin [22] for velocity statistics.

The case 16S in Table 2 is comparable to the case 1KMM in Table 1. Both cases correspond to an averaging time roughly 2 times longer than the one in Galantucci and Quadrio [1], with snapshots taken at a similar frequency for all those cases. Thus, the case 16S gives a lower bound for the sampling error in Galantucci and Quadrio [1]. The Figure 1 shows the normalized sampling error associated with various statistical quantities for the cases present in Table 2.

Figure 1: Normalized sampling error for the cases in Table 2. Top: $E[\theta]$. Middle: $E[\theta'^2]$ (left) and $E[\varepsilon_\theta]$ (right). Bottom: $E[\theta'^4]$ (left) and $E[\varepsilon_\theta^2]$ (right).

The clear trend in Figure 1 is that higher order moments are associated with higher sampling errors. Regarding the plots on the middle row, the normalized sampling error for the temperature variance and for the mean dissipation rate have a similar amplitude and involve turbulent quantities to the power 2. Qualitatively, the situation is similar on the plots in the bottom row, which involve turbulent quantities to the power 4.

Regarding case 16S, the magnitude of the normalized sampling error is around 5% for $E[\theta]$, except in the middle of the channel, where it gets close to 100% as the average temperature is zero. It also drops down to zero at the walls as the temperature is imposed there (Dirichlet boundary condition, $\theta = \pm 1$). For cases 18S and 18L, the imposed temperature at the walls is zero, so both the sampling error and the average temperature tend to zero there. The resulting normalized sampling error $E[\theta]$ at the wall for those cases is around 0.2%.

Focusing on case 16S for higher order integral statistics, the normalized sampling error reaches almost 10% for $E[\theta'^2]$ and $E[\varepsilon_\theta]$, and even 15% for $E[\theta'^4]$ and $E[\varepsilon_\theta^2]$. These results show that the differences of 7% on the average of ε_θ on different grid reported in Galantucci and Quadrio [1] is well within the sampling error as their simulations have the same domain extension but a duration halved compared with the case 16S.

Using the Central Limit Theorem applied to weakly correlated samples described in Oliver et al. [25] (Theorem 27.4 in Billingsley [26]), the sampling error decreases with the square root of the number of samples. For a given sampling frequency, the error is therefore halved when the duration of the simulation (and the number of samples) is increased by a factor 4. This holds quite well when comparing cases 16S and 16L, or 18S and 18L. Overall, significant reduction of the sampling error can be achieved using extended computational domains and / or simulations with a longer duration.

Scalar field	$Nx * Ny * Nz$	θ	θ'^2	θ'^3	θ'^4	ε_θ	$\varepsilon'_\theta{}^2$
1KMM	40 * 129 * 60	-7.18	-5.02	-4.42	-3.67	-6.68	-1.26
2GQC	64 * 129 * 64	-9.15	-7.14	-6.50	-5.43	-7.82	-1.91
3S	112 * 129 * 80	-11.8	-10.5	-8.57	-8.11	-9.54	-3.25
4VK	112 * 181 * 80	-11.8	-10.5	-8.58	-8.13	-9.98	-3.29

Table 3: $\log_{10}$ of the quadratic relative error for various quantities.

200 4. Impact of unresolved smaller scales on statistics

In this section, we investigate the impact of unresolved smaller scales on various quantities. First, we investigate dimensionless bulk quantities. Using the scalar with the finest resolution (6S) as a reference, we can compute a quadratic relative error. For instance, the quadratic relative error for the average temperature on the grid 1KMM is defined by:

$$\frac{\int_{y=-1}^{y=1} [\overline{\theta_{1KMM}}(r) - \overline{\theta_{6S}}(r)]^2 dr}{\int_{y=-1}^{y=1} \overline{\theta_{6S}}(r)^2 dr} \quad (6)$$

In Table 3, the quadratic relative error is given for various quantities. Looking at the relative error for the moments of the temperature (θ , θ'^2 , θ'^3 and θ'^4), one can extract two trends. First, for all resolutions considered, the higher the moment, the higher the relative error. Second, the finer the resolution, the closer to the case 6S. The resolution 1KMM seems sufficient to accurately estimate the average temperature. However, accurate estimation of higher order moments requires a finer resolution as unresolved smaller scales have a higher impact on them. The situation is similar for ε_θ and $\varepsilon'_\theta{}^2$: the first is relatively well estimated by the coarsest grid while the second has a stronger dependence on unresolved smaller scales.

It is important to stress that the discretization error in Table 3 is typically several decades lower than the sampling error. However, all the scalar fields are transported by the same velocity field. Therefore, they are strongly correlated

and are all plagued by the same sampling error. This allows us to exhibit the
 215 impact of **unresolved** smaller scales on statistics, even though this impact is
 relatively small compared with the sampling error.

For the turbulent channel flow studied here, at the wall, the temperature
 is imposed ($\theta = \pm 1$) and the temperature evolution equation 4 contains no
 source term. As a result, the exact average temperature derivative at the wall
 is plagued by statistical uncertainty and depends on the spatial resolution. We
 define the friction temperature θ_τ and the reference temperature θ_{ref} with:

$$\theta_\tau = \frac{1}{Re_\tau Pr} \partial_y \bar{\theta} \left(\pm \frac{L_y}{2} \right) \text{ and } \theta_{ref} = \frac{1}{Re_\tau Pr} \frac{\bar{\theta}(L_y/2) - \bar{\theta}(-L_y/2)}{L_y} \quad (7)$$

The theoretical value of the friction velocity, which is equal to one here,
 produces a θ_{ref} not plagued by statistical uncertainty, while θ_τ is. Therefore, we
 use θ_{ref} to rescale the temperature statistics. Spatial derivatives are expressed
 220 in wall-units using the theoretical value of the friction velocity. For convenience,
 plots are using a wall-normal distance in **computational** units ($y \in [-1, 1]$).

Complementary with the bulk quantities in Table 3 and the integral profiles
 of ε_θ or its variance, we investigate the anisotropy of the fluctuating temperature
 gradient. This is done using the barycentric map defined by Banerjee et al. [27].
 Given a symmetric positive semi-definite tensor M_{ij} , the associated (traceless)
 anisotropy tensor is

$$\widetilde{M}_{ij} = \frac{M_{ij}}{M_{kk}} - \frac{1}{3} \delta_{i,j} \quad (8)$$

The eigenvalues of $\widetilde{M}_{ij}$, λ_k , verify $\lambda_1 \geq \lambda_2 \geq \lambda_3$. Based on those eigenvalues,
 Banerjee et al. [27] define 3 limiting states forming a basis: one-component (1C),
 two-component (2C) and three-component (3C). The number of components
 225 corresponds to the number of non-zero eigenvalues of M_{ij} . In the state 3C,
 all three eigenvalues are equal: the tensor is isotropic. In the state 2C, one
 eigenvalue is negligible while the two others are equal: the anisotropy is two-
 dimensional. In the state 1C, two eigenvalues are negligible: the anisotropy is
 one-dimensional.

In the barycentric map, each limiting state is the vertex of an equilateral
 triangle. For any symmetric positive semi-definite tensor M_{ij} , there is a unique

point inside this equilateral triangle with coordinates

$$[x, y] = (\lambda_1 - \lambda_2) [x_{1C}, y_{1C}] + 2(\lambda_2 - \lambda_3) [x_{2C}, y_{2C}] + (3\lambda_3 + 1) [x_{3C}, y_{3C}] \quad (9)$$

230 where $[x_{iC}, y_{iC}]$ is the coordinate of the vertex corresponding to the limiting state iC. Following Lumley and Newman [28], it is possible to visualize the anisotropy of a traceless tensor using its second and third invariants. However, the resulting invariant map is distorted as those invariants are nonlinear functions of the tensors elements. The barycentric map is connected to the invariant
 235 map with a bijection and does not suffer from this bias. This is the main motivation for the present choice; interested reader will find a deeper analysis of the barycentric map in Banerjee et al. [27].

The symmetric positive semi-definite tensors investigated here are related to the temperature derivatives. The first tensor investigated, $\overline{\partial\theta} = \overline{\partial_i\theta'\partial_j\theta'}$,
 240 is relevant to this study as its trace is proportional to the scalar dissipation rate ε_θ and its anisotropy is related to the anisotropy of the fluctuating temperature gradient. The other tensor investigated is the variance of $\overline{\partial\theta}$: $\sigma_{\overline{\partial\theta}} = \overline{[\partial_i\theta'\partial_j\theta']^2} - [\overline{\partial_i\theta'\partial_j\theta'}]^2$. Locations where the fluctuating temperature gradient is isotropic correspond to points of the barycentric map closer to the vertex 3C
 245 of the triangle. The further away from this vertex, the higher the anisotropy. Points closer to 1C or 2C correspond to one-dimensional or two-dimensional fluctuations, respectively. It is important to stress that the barycentric map does not provide a complete description of the anisotropy as it obliterates the eigenvectors associated with the eigenvalues.

250 The **left frame of** Figure 2 is in agreement with Table 3; the profiles of ε_θ do not show any significant impact of **unresolved** smaller scales in 1KMM and 3S results. The situation is similar for the barycentric map of the anisotropy of $\overline{\partial\theta}$ (**right frame of** Figure 2). Due to the imposed temperature at the wall, the anisotropy at the boundary has only one component (limiting state 1C). Then,
 255 the closer to the middle of the channel, the closer to isotropy (limiting state 3C).

Focusing on the left frame of Figure 2, one may notice that the profiles of

Figure 2: Dissipation rate $\overline{\varepsilon_\theta}$ (left) and barycentric map associated with $\overline{\frac{\partial \theta}{\partial \theta}}$ (right).

ε_θ are not exactly symmetric. This is not an issue here as this is well within the sampling error, which is around 10% for ε_θ , according to Figure 1. However, performing a simulation with a duration long enough to have a negligible sampling error, one may obtain a profile that still lacks symmetry. This is specific to the combination of smaller domains and periodicity used here: global mixing between the lower and upper half of the domain is not perfect due to the absence of large scale structures.

Figure 3: 95% confidence interval of the variance of the dissipation rate ε_θ (left) and barycentric map associated with $\sigma_{\frac{\partial \theta}{\partial \theta}}$ (right).

265 The left frame of Figure 3 is also in agreement with Table 3; the variance of ε_θ is significantly impacted by unresolved smaller scales, and the coarsest grid underestimates this quantity, especially outside of the viscous sublayer where the discretization error is as large as the sampling error. Closer to the wall, this impact is less visible and all spatial resolutions produce a similar variance

270 of ε_θ . The barycentric map of the anisotropy of $\sigma_{\overline{\partial\theta}}$ also shows the impact of unresolved smaller scales. In the middle of the channel ($y = 0$), the coarsest grid gives a similar weighting for all limiting states (1C, 2C and 3C), this correspond to the part of 1KMM closer to the middle of the triangle. At this location of the channel ($y = 0$), finer grids give a similar weighting only for the limiting states

275 1C and 3C, but a negligible weight to state 2C, this correspond to the part of 6S and 3S closer to the edge connecting 1C and 3C.

Figure 4: Spectra of the streamwise (left) and spanwise (right) contributions to the scalar dissipation rate ε_θ at $y = 0$ (middle of the channel).

Integral quantities provide only a limited amount of information and spectra in Figure 4 are more insightful. They are taken at the middle of the channel ($y = 0$). The spanwise spectra show that the spanwise contribution to ε_θ is well

280 resolved even on the coarsest grid. However, this grid is not isotropic and it has extended cells in the streamwise direction ($\Delta_x^+ = 17$, $\Delta_z^+ = 6$ for 1KMM). This leads to a pronounced bump on the streamwise spectrum of 1KMM at the highest resolved wavenumbers ($k_x^+ \approx 0.2$). As one can notice, the streamwise

spectrum of 3S also has a bump at the highest resolved frequency ($k_x^+ \approx 0.55$).
 285 However, regarding the latter case, this has a negligible impact on the statistics
 of ε_θ because the bumps correspond to very high frequencies for which the
 streamwise contribution to the dissipation is two decades smaller than its peak
 value around $k_x^+ \approx 0.05$. This does not hold for case 1KMM: the bump on the
 streamwise spectrum is present at lower frequencies, for which the streamwise
 290 contribution to the dissipation has a magnitude similar to the one at the peak.
 This explains the severe impact of **unresolved** smaller scales on the variance of
 ε_θ exhibited in Figure 3.

Figure 5: Instantaneous scalar gradient ($\sum \partial_i \theta'^2$) in **computational** units at $y = 0$ (middle of the channel). Logarithmic colormap. Left: 1KMM. Right: 6S.

Figure 5 illustrates the impact of the under-resolution on the gradient of the scalar. On the one hand, both fields exhibit similar structures at larger
 295 scales, in agreement with the ability of the grid 1KMM to estimate the average
scalar dissipation rate, as shown in Figure 2. On the other hand, smaller scales
 are visibly misrepresented on the coarser grid, as the picture on the left is
 plagued by the oscillations, which correspond to the wavenumbers of around
 $k^+ = 0.2$ that are overpredicted in 1KMM results shown in **the left frame of**
 300 Figure 4. This is consistent with the previous results: the grid 1KMM is too
 coarse to properly resolve the sharp gradients which separate dissipative and
 non-dissipative regions.

5. Conclusion

The present investigation demonstrates the impact of a limited resolution
305 of the smaller scales on the scalar dissipation rate, its variance and on the
anisotropy of the fluctuating scalar gradient. In a preliminary part, we showed
that simulations of the turbulent channel flow based on smaller domains and
with a limited duration (often used to perform grid sensitivity analysis) are
plagued by a relatively large sampling error, especially for higher order moments
310 like the scalar dissipation rate or its variance. This sampling error is often larger
than the discretization error, thus preventing accurate estimation of the latter,
except for simulations with an extended domain and duration.

In the present study, this situation is overcome by using a single veloc-
ity field to transport several passive scalars with different resolutions: all the
315 scalars are strongly coupled by the velocity field and plagued by the same sam-
pling error. The resulting difference between the scalars is solely due to the
discretization error, which can thus be estimated. Another workaround could
be to perform simulations with a duration long enough so that the sampling
error becomes negligible compared with the discretization error, or to perform
320 many simulations with slightly distinct initial conditions, followed by ensemble
averaging.

Regarding the key integral turbulence statistics of the passive scalar inves-
tigated here, our results confirm that previous DNS based on a pseudo-spectral
method with the resolution 1KMM (Kim et. al. [2], Kasagi et al. [13], Tiselj
325 et al. [19]) can estimate the average temperature, its variance and the average
scalar dissipation rate with a relatively low discretization error, as indicated
Table 3. However, they can only provide qualitative estimation for higher or-
der moments. To accurately estimate those higher order moments, finer grids
must be used. Regarding the variance of the scalar dissipation rate, or the
330 anisotropy of the fluctuating scalar gradient, the grid recommended by Vreman
and Kuerten [3] is sufficient for pseudo-spectral schemes (6th order compact
finite-difference schemes typically require a grid 4/3 finer). Our results do not

preclude existence of scalar structures or events, which are too small to be resolved with the Vreman and Kuerten resolution. However, our results show
 335 that these events might **significantly** affect only the **integral** turbulence statistics higher than fourth-order. **It is important to stress that a small event can impact part of the PDF of a turbulent quantity without significantly affecting the associated integral value.**

Our results also **suggest** that **unresolved** smaller scales have a stronger impact
 340 outside of the viscous sublayer, and have almost no impact closer to the wall. Strictly speaking, this observation is valid only for the Dirichlet boundary condition investigated here (imposed temperature), and may not hold for a Neumann boundary condition (imposed heat flux), a Robin boundary condition (heat exchange coefficient) or conjugate heat-transfer (fluid-solid thermal coupling).
 345 Regarding the latter case, the present analysis will provide a solid ground for future investigations on the discontinuity of ε_θ at the fluid-solid interface.
