Abstract

We report on the observation of strongly anisotropic surface acoustic wave propagation on nanostructured thin films. Two kinds of tungsten samples were prepared by sputtering on a silicon substrate: a conventional thin film with columns normal to the substrate surface, and an oriented columnar architecture using the glancing angle deposition (GLAD) process. Pseudo-Rayleigh waves (PRWs) were imaged as a function of time in x and y directions for both films thanks to a femtosecond heterodyne pump-probe setup. A strong anisotropic propagation as well as a high velocity reduction of the PRWs were exhibited for the GLAD sample. For the wavevector $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ the measured group velocities v_x and v_y equal 2220 m s^{-1} for the sample prepared with conventional sputtering, whereas a strong anisotropy appears ($v_x = 1600 \text{ m s}^{-1}$ and $v_y = 870 \text{ m s}^{-1}$) for the sample prepared with the GLAD process. Using the finite element method, the anisotropy is related to the structural anisotropy of the thin film's architecture. The drop of PRWs group velocities is mainly assigned to the porous microstructure, especially favored by atomic shadowing effects which appear during the growth of the inclined columns. Such GLAD thin films constitute a new tool for the control of the propagation of surface elastic waves and for the design of new devices with useful properties.

Keywords: glancing angle deposition, columnar films, acoustics, pump-probe setup, anisotropy

1. Introduction

For the last few decades, numerous works have been focused on the wave propagation in anisotropic media [1–3]. This sign of interest is mainly assigned to the exciting range of properties, which can be reached by only changing the probing direction in the material. Among the solid materials, assessment of anisotropy can be significantly evidenced in metals since all metallic crystals are intrinsically anisotropic due to the directional differences in inter-atomic stiffness bonds in the crystal structure [4]. However, in many typically prepared

metals, the material is formed from randomly oriented crystals, which is conventionally defined as a polycrystalline structure. Consequently, these individual crystals are randomly oriented, leading to physical behaviors at the macroscopic scale which are non-dependent on the direction.

In the case of thin film materials, the anisotropic properties may become significant since these nearly-2D systems can adopt various designs, texture patterns and architectures depending on the fabrication method [5–7], particularly for metallic, semiconducting or dielectric thin films prepared by the glancing angle deposition (GLAD) method [8–10]. Due to

the anisotropic microstructure of the inclined columnar architecture typically produced by the oriented growth, many physical properties of GLAD films such as optical indices [11], electrical conductivity [12], wetting [13], friction coefficient [14] and so on, have shown in-plane anisotropic behaviors when they are probed in the growing direction or perpendicularly to the columns. Such anisotropy of the film properties is mainly related to the progressive broadening of the columns in the orthogonal direction to the deposition plane. By favoring an oriented growth of columnar architectures, this GLAD method also represents an original strategy and an attractive ability to produce and engineer surface behaviors in a one-step deposition process.

In this paper, we report on the surface acoustic wave propagation measured with a femtosecond heterodyne pump-probe setup in tungsten (W) thin films sputter-deposited on (100) silicon wafer by conventional sputtering and GLAD process. The influence of an inclined columnar architecture on the propagation of elastic waves in tungsten films compared to a classical structure (columns, which are normal to the substrate surface) motivates this work. Simulations with simplified models based on periodic structures are presented. The correlation between the anisotropic acoustic wave velocity and the films' microstructure is demonstrated.

2. Materials and methods

Tungsten films were deposited on a (100) Si wafer by DC magnetron sputtering from a metallic target (51 mm diameter and 99.9 at.% purity) inside a home-made vacuum chamber. The experimental device was a 40 l sputtering chamber pumped down via turbo-molecular pump backed by a primary pump, allowing a residual vacuum of about 10^{-6} Pa. The tungsten target was sputtered with an argon flow rate of $2.3 \text{ cm}^3 \text{ min}^{-1}$ and a constant pumping speed of 13 L s^{-1} , which produced an argon sputtering pressure of 3.0×10^{-1} Pa. The target current was fixed at 100 mA and the deposition time was adjusted, so as to get a film thickness of 300 nm. No external heating was applied during the growth stage and depositions were carried out at room temperature. The GLAD technique [15] was implemented, in order to produce normal and tilted columnar architectures. It consists of depositing thin films under conditions of obliquely incident flux of the sputtered particles and on a fixed or mobile substrate. In this study, two incident angles were used: $\alpha = 0^\circ$ (conventional sputtering) and 80° (GLAD technique). Scanning electron microscopy (SEM) was used to view the surface and the fractured cross-section of the films with a JEOL JSM 7800 field emission SEM.

Measurements of the acoustic waves propagation are performed with a femtosecond pump-probe setup [16, 17]. The acoustic generation into the tungsten film is done by the optical absorption of one femtosecond laser beam, namely the 'pump'. Consequently, a fast temperature increase appears inducing acoustic waves via thermoelastic effect [18]. The surface reflectivity change contains the acoustic and thermal contributions. These reflectivity changes are probed by a second laser beam, namely the 'probe'. In order to acquire the

Table 1. Properties of silicon and tungsten used for calculations.

Material	ρ (kg m ⁻³)	c_{11} (GPa)	c_{12} (GPa)	c_{44} (GPa)
Silicon (Si)	2330	166	63.9	79.6
Tungsten (W)	19300	501	198	151.4

temporal reflectance response of the film, two femtosecond lasers are used in our setup with a heterodyne configuration aka asynchronous optical sampling. The lasers are electronically synchronized with a controlled frequency shift in their repetition rates (48 MHz and 48 MHz + 700 Hz). This gives rise to an additional time difference between the pump and the probe of about 300 fs for each pump excitation (every 20.8 ns). Compared to traditional pump-probe setups using a mechanical delay line, this technique removes the mechanical vibrations and the variations in size of the focal spot due to a slight divergence/convergence of the optical beam. It also allows a whole time spanning of 21 ns with a resolution of about 1 ps. At the output of the lasers, the duration of the pulses is 180 fs. The central wavelength of the beams is 515 nm (frequency doubled Yb:YAG lasers). The two beams are focused on the sample surface and the resulting radii ($1/e^2$) of the spots' size is around $1 \mu\text{m}$. For a map of the acoustic signal at the surface of the film, the pump spot is scanned by means of a lens set controlled with a 2D translation stage in the pump optical path. The scan of the pump spot is performed over an area of $50 \times 50 \mu\text{m}^2$.

Numerical simulations of the surface acoustic wave propagation are performed with the finite element method. The physical parameters as mass densities and elastic constants of silicon and tungsten are given in table 1, keeping in mind that elastic constants may differ from the bulk material, especially for thin films [19]. Unit cells are described and explained in part 3. Bloch-Floquet periodic conditions are applied on boundaries external to the unit cell, both in x and y directions according to equation (1):

$$u_j \left(\vec{P} + a_l \vec{r}_l \right) = \exp(ik_j a_l) \cdot u_j \left(\vec{P} \right) \quad (1)$$

where u_j is the displacement in the x , y or z direction, vector $\vec{P}$ represents the position, a_l is the period, vector $\vec{r}_j$ is the unitary vector and k_j the wavevector in the x or y direction depending on the boundary. The x and y directions correspond to the crystallographic axes. These structures are therefore simulated to be infinitely periodic in both directions. Bottom boundaries of the models are mechanically set as fixed. Dispersion curves are obtained by varying the wavevector k in the range of interest in the two directions.

3. Experimental results

SEM observations of as-deposited tungsten thin films produced by conventional sputtering ($\alpha = 0^\circ$) exhibit a dense and polycrystalline (x-ray diffraction not shown here) columnar microstructure, which is perpendicular to the substrate surface (figures 1(a) and (b)). This morphology is typical of sputtered metallic films and corresponds to the first zone of classical structural zone models [20, 21]. A fine fiber texture develops

Figure 1. Schematic views with cross-section and surface SEM observations of as-deposited tungsten thin films 300 nm thick sputter-deposited by (a) conventional dc magnetron sputtering and (b) GLAD process. An incident angle $\alpha = 80^\circ$ of the particle flux was used for GLAD films. Arrows indicate the incoming flux of tungsten atoms, which leads to an inclined columnar architecture (column angle $\beta = 43^\circ$). Inset in figure (b) depicts the elliptical section (dotted line) of the inclined columns with a significant porous structure following the x direction.

in pure elemental films sputter-deposited at room temperature. Due to the high melting point T_m of tungsten (3695 K at 1 atm) and no external heating during deposition (the substrate temperature T_s increases a few degrees at the end of the growth), the temperature T_s/T_m ratio is lower than 0.1, which corresponds to the first zone of the structural zone models. This kind of film typically exhibits density close to 95% of the bulk material and isotropic behaviors.

For tungsten films prepared by the GLAD process with an incident angle $\alpha = 80^\circ$, a well-defined and inclined polycrystalline columnar microstructure is clearly viewed from the cross-section SEM observation (figure 1(b)) with a column angle $\beta = 43^\circ$. This difference between α and β angles is commonly met in GLAD films, and is also assigned to the shadowing effect and diffusion of the particles on the growing film. Similarly, the surface observation shows a voided and corrugated surface (figure 1(b)). From this top view, one can see asymmetric and elongated holes between columns. Such columns also show an elongated shape with a long axis, which is perpendicular to the direction of the incoming particle flux (white arrow). These anisotropic structural characteristics have already been reported by Tait *et al* [22]. They are mainly connected to the geometric shadowing effect and a favored diffusion of the incoming sputtered atoms in the direction

perpendicular to the incidence of the particle flux. This atypical growth, specific to oblique angle deposition, leads to elliptical columns with their long axes perpendicular to the plane of incidence. Increasing the film's thickness produces chains of columns [23], which are transverse to the particle flux direction, as illustrated in figure 1(b). As a result, the column is able to grow along the y direction, which leads to a progressive fanning of the column cross-section. With such a fanning of the individual columns, the lateral growth allows neighboring columns to be in contact and chain together. This gives rise to a preferential bundling of the columnar microstructure following the y direction. Chaining and fanning phenomena produce elliptical shapes of the columnar cross-section and thus, a significant structural anisotropy is developed. The latter generates a corresponding anisotropy in the acoustic wave propagation, as shown in figure 2. The wave amplitude obtained from the pump-probe measurements is chronologically illustrated after 200 ps and until 6 ns for conventional films ($\alpha = 0^\circ$) and those prepared by GLAD ($\alpha = 80^\circ$). It is worth noticing the circular and concentric rings observed for conventional films (anisotropy of silicon has a very weak influence), whereas elliptical shapes are clearly viewed for inclined columnar structures. The anisotropic propagation is thus evidenced and intimately connected to the microstructural anisotropy of tungsten films produced by the GLAD process.

Figure 3 shows the relative variation of the reflectivity ($\Delta R/R$) as a function of time, along the x direction for the tungsten films with sputter-deposition ($\alpha = 0^\circ$). The thermal background has been subtracted; the $\Delta R/R$ color bar scale gives the level of the acoustic part of the signal. Two different wave packets are observed. The integral of the squared relative reflectivity over the time was calculated for each wave packet. It gives information about how the elastic energy decreases as the wave propagates. For the slowest wave, it is found to decrease proportionally to the inverse of the distance. This is typical of a surface wave and, considering the symmetry of the source, this wave is a pseudo-Rayleigh wave. On the other hand, for the fastest wave, it is inversely proportional to the square of the distance, indicating this wave to be the skimming longitudinal one (surface part of the volume longitudinal wave). The pseudo-Rayleigh wave is very dispersive (velocity strongly frequency dependent). Similar measurements have been performed for the x and y directions for tungsten films prepared by the GLAD technique using $\alpha = 80^\circ$ (not shown here).

The dispersion curves (figure 4) have been obtained by plotting the FFT-2D (2 dimensions discrete Fourier transform) of the relative reflectivity versus time and position as typically shown in figure 3. The local slope of these dispersion curves directly corresponds to the group velocities. The short laser pump pulses excite waves with frequencies in the GHz range and with wavelengths of a few micrometers. The dispersive behavior of the pseudo-Rayleigh waves is also observed in figure 4 since the frequency versus wave number plots do not exhibit a linear behavior. For tungsten films prepared by conventional sputtering ($\alpha = 0^\circ$), dispersion curves are very similar following x and y directions (figures 4(a) and (b))

Figure 2. Surface acoustic wave propagation after 200 ps, 1, 4 and 6 ns measured with the femtosecond heterodyne pump-probe setup in normal ($\alpha = 0^\circ$) and inclined ($\alpha = 80^\circ$) columnar tungsten thin films on (100) Si substrate. The wave amplitude exhibits circular and concentric rings for conventional films ($\alpha = 0^\circ$), whereas elliptical shapes are clearly observed for inclined films due to an anisotropic propagation.

Figure 3. Variation of the relative reflectivity $\Delta R/R$ (after removing the thermal part) versus time and pump-probe distance for conventional tungsten films sputter-deposited with $\alpha = 0^\circ$ and following the x direction. Skimming longitudinal and pseudo-Rayleigh waves are indicated. The pseudo-Rayleigh wave exhibits a significant dispersive behavior. To increase the temporal length, the wave from the previous pulse (red rectangle) was shifted one period later.

indicating an expected isotropic in-plane behavior as tungsten columns are perpendicular to the film/substrate interface and randomly distributed on the substrate surface.

For GLAD films prepared with $\alpha = 80^\circ$ (column angle $\beta = 43^\circ$), skimming longitudinal waves cannot be observed because of a low signal-to-noise ratio, whereas pseudo-Rayleigh waves are clearly seen for x and y directions (figures 4(c) and (d), respectively). It is also worth noting that the group velocities are far lower than the ones with conventional sputtering ($\alpha = 0^\circ$) films. In addition, the $\Delta R/R$ is significantly reduced, which may come from a more absorbing medium. Figures 4(c) and (d) clearly indicate that the pseudo-Rayleigh wave propagates at a lower velocity in the x direction, showing

Figure 4. Dispersion curves for x (a) and (c) and y (b) and (d) directions obtained from the variation of relative reflectivity versus spatial and time frequencies for (a) and (b) $\alpha = 0^\circ$ and (c) and (d) $\alpha = 80^\circ$. Skimming longitudinal and pseudo-Rayleigh waves are both noticeable for conventional films ($\alpha = 0^\circ$ and $\beta = 0^\circ$) whereas only pseudo-Rayleigh waves are clearly observed for GLAD films ($\alpha = 80^\circ$ and $\beta = 43^\circ$). Frequencies and wave numbers corresponding to the highest power spectral density (dark red level on normalized spectral reflectivity scale) have been used to determine the acoustic propagation.

a relevant anisotropy. Assuming these dispersion curves, the velocity was calculated for a wavevector $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$. This value of wave number k corresponds to the highest signal produced from the relative reflectivity measurements (maximum of energy). For all samples, group velocities v_g of pseudo-Rayleigh waves are reported in table 2. The same velocity is

Table 2. Group velocities of pseudo-Rayleigh waves (at $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$) along x and y axes in tungsten thin films sputter-deposited by the conventional process ($\alpha = 0^\circ$) and GLAD technique ($\alpha = 80^\circ$).

Incident angle α ($^\circ$)	Column angle β ($^\circ$)	Velocity v_g (m s $^{-1}$)	
		x axis v_x	y axis v_y
0 ± 2	0 ± 3	2220 ± 50	2200 ± 50
80 ± 2	43 ± 3	870 ± 50	1600 ± 50

nearly obtained along x and y axes for conventional ($\alpha = 0^\circ$) tungsten films ($2220 \pm 50 \text{ m s}^{-1}$ and $2200 \pm 50 \text{ m s}^{-1}$, respectively). The measured velocity of the front of the wave (first detected crest) is in the order of 3750 m s^{-1} at a distance of $40 \mu\text{m}$. It is 40% higher than the surface wave velocity computed from the elastic constants of bulk tungsten (2646 m s^{-1} along $[100]$ crystallographic direction [24]). This difference is mainly assigned to the contribution of the silicon substrate in which the surface wave velocity is 4917 m s^{-1} along the $[001]$ direction [24] and thus increases the pseudo-Rayleigh wave velocity since the thickness of the film is only 300 nm .

A substantial drop of velocity is obtained for GLAD tungsten films with $v_x = 870 \text{ m s}^{-1}$ and $v_y = 1600 \text{ m s}^{-1}$ along x and y directions, respectively. Such a drop is related to the voided microstructure, which becomes relevant when the incident angle α of the particle flux tends to 90° . Due to the shadowing effect at the atomic scale, the increased shadow lengths increase the inter-island separation during the first growing stage. As a result, a larger fraction of the film microstructure consists of voided regions. The film density becomes especially sensitive to α in the extreme shadowing regime (i.e. $\alpha \geq 70^\circ$) where an isolated column microstructure develops and increases the average intercolumn spacing. A very high porosity can be developed in GLAD films. The voided fraction may be higher than 70%, particularly when the incident angle α reaches glancing values (i.e. higher than 70 – 80°). As a result, the film density can be lower than 30% of the bulk material [25]. In our GLAD tungsten films, the inclined columns disturb the wave propagation at columns interfaces due to the voided microstructure. The significant difference between v_x and v_y is linked to the structural anisotropy, which develops in the film plane. This anisotropy corresponds to an elliptical shape of the columns cross-section (inset in figure 1(b)) with their long axes perpendicular to the plan of incident of the particle flux [23]. As the film thickness increases, elliptical and inclined columns grow with connections to each other by chains perpendicular to the plane of incidence or to the direction of shadowing [26]. This chains formation (y direction in figure 1(b)) creates pathways for the wave propagation, whereas a porous architecture is more pronounced in the x direction. These anisotropic properties of the surface acoustic wave propagation agree with other anisotropic behaviors previously reported by others about optical [27] and electrical characteristics [28, 29]. These directionally dependent properties are thoroughly associated to the anisotropic structure, which is characteristic of inclined columnar GLAD films.

Figure 5. Scheme of (a) the first and (b) second unit cell composed of (100) Si substrate (grey) and tungsten (black). The main dimensions are indicated in the figure, the height of the silicon block is not to scale. (c) Basic scheme of the tungsten (grey) and holes (green) distribution with several periods. The second unit cell is plotted in transparent blue, and the simulated holes in transparent red.

4. Computational results and discussion

The finite element method is used to simulate the wave propagation for the two samples in order to better understand this anisotropic propagation. Figures 5(a) and (b) show the two-unit cells studied in this paper. They both consist of a silicon block with a square base of width $a = 500 \text{ nm}$ and height $h_{\text{Si}} = 25 \mu\text{m}$ (not on scale on schematics), on which lies a tungsten layer. Two different architectures of tungsten thin films are studied: (a) a homogeneous square block (same width a as the silicon) of height $h = 300 \text{ nm}$, (b) an inclined block with a square base (with the same width a) of height $h = 300 \text{ nm}$ and an inclination angle $\beta = 43^\circ$. Two inclined holes with a rectangular base of length $c = 450 \text{ nm}$, width $d = 100 \text{ nm}$, height $h = 300 \text{ nm}$ and inclination angle $\beta = 43^\circ$, separated by a distance $a/2 = 250 \text{ nm}$, are dug in the inclined tungsten block. This geometry leads to a porosity of 36% (holes-induced micro-porosity). Two infinite periodic structures are therefore simulated based on these schematics. The design of the unit cell of the second sample (see figure 5(b)) is built as a simple model of the tungsten layer obtained with the GLAD technique. Based on observations from the SEM picture shown in figure 1, the thin film structure is modeled as a network of inclined tungsten columns randomly overlapped. In order to simplify the simulation and provide a clear interpretation of the wave propagation, the structure is simulated to be infinitely periodic with Bloch-Floquet conditions (see equation (1)) regarding x and y directions as presented

Figure 6. (a) Calculated band diagram of the first unit cell. Only the four first modes are shown on the band diagram. (b) The distributions of displacement of the three first modes are shown for a wave number $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$. The colors indicate the total displacement. The black arrow indicates the direction of propagation and the red arrow the polarization.

in figure 5(c). Dimensions of the columns and their distributions, i.e. of the holes and their distributions, are chosen accordingly to the sizes measured from the SEM picture (inset in figure 1(b)).

Figure 6(a) presents the band diagram of the first unit cell as well as (b) the distribution of displacements for three different eigenmodes. Calculations are performed for a propagation in the x direction. Due to the symmetry of the structure, and of the crystallography of tungsten, the same results are obtained for a propagation in the y direction. In the dispersion curves, only the four first eigenmodes are shown. They consist of the three first SAWs and the first bulk mode. The first mode corresponds to the pseudo-Rayleigh wave, as experimentally observed. This mode is polarized in the sagittal plane, with a counter clockwise rotation of its polarization regarding to the direction of propagation. The calculated group velocity of the wave at $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ is $v_x = v_y = 2130 \text{ m s}^{-1}$, which is close to the experimental data. An inflexion point located at around $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ is visible on the dispersion of this mode. This transition is linked to the stacking of the two materials: at low wave numbers, the propagation of the pseudo-Rayleigh wave is deeply linked with the silicon substrate, whereas for higher wave numbers, the wave is more confined in the tungsten part and the influence of the silicon substrate is negligible. The location of the inflexion point is straightforwardly connected to the tungsten thickness, which

may experimentally vary and may contribute to the differences between experimental and numerical speeds. Moreover, it is well known that thin films properties are slightly different than bulk ones. The second mode is the Love wave, namely the pseudo-shear wave polarized in the y direction. This mode is not experimentally observed either due to the source, for which its symmetry may not allow its excitation or because of the detection process. The third mode is the Sezawa mode (pseudo-Rayleigh M2). It is similarly polarized to the pseudo-Rayleigh mode, but the polarization turns in the other direction (clockwise regarding to the direction of propagation). Again, this mode is not experimentally observed because of the symmetry of the source and/or it is too close to the fourth mode as well. Such a mode (black in the dispersion diagram) is the skimming longitudinal mode, which is the slowest bulk mode. The displacement of this mode is not shown as it is sensitive to the bottom boundary condition of the silicon substrate. Yet, the dispersion of this mode seems to be in good agreement with the experimental dispersion measured for the second mode.

Figure 7(a) presents the dispersion of the two pseudo-Rayleigh mode following the x (red) and y (blue) directions, as well as their displacements (figure 7(b)) calculated for the second unit cell. Whereas the pseudo-Rayleigh mode corresponds to the first eigenmode for the propagation following x , it corresponds to the second eigenmode for the propagation in the y direction. A small transverse polarization along the x direction is noted for this Rayleigh mode (propagating following the y direction), coming from the inclination of the holes. Yet, calculations were also done for a structure with the same straight holes. The second eigenmode (following the y direction) was also found to be the pseudo-Rayleigh one, without any x polarization, corroborating the study of this mode for the second unit cell. A strong anisotropy is obtained between the two directions, as well as a more pronounced dispersion. The calculated group velocities at $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ are $v_x = 1720 \text{ m s}^{-1}$ and $v_y = 2350 \text{ m s}^{-1}$, which gives an anisotropy ratio of 73%. The propagation of the modes is highly affected by the implementation of the holes, which lead to their folding. Anisotropy has to be linked to the rectangular shape of the holes, which does not similarly disturb the propagation of the waves in the two directions. Supplementary simulations, not shown in this paper, were carried out to study the influence of the different geometrical parameters. Results showed that the key parameter in the folding of the mode propagating in the x direction is the length of the hole regarding to the period a . Very similar results were found for the same structure with the same holes, but normally dug to the silicon surface, meaning that the inclination only plays a little role in the anisotropy. As a result, the driving force remains the shape of the holes and the choice of the period a . It is interesting to note that the speed at $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ of the pseudo-Rayleigh wave propagating following the y direction is slightly higher than the one propagating in the homogeneous tungsten block. At this given wavevector, the wave is not confined in the tungsten block and the silicon still influences the propagation, as shown in the distribution of displacement. Hence, by removing a part of tungsten (holes

Figure 7. (a) Calculated band diagram of the second unit cell for the x and y directions. Only the pseudo-Rayleigh modes are shown on the band diagram. (b) The distributions of displacement of the pseudo-Rayleigh modes propagating in the two directions are shown for a wave number $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$. The colors indicate the total displacement. The black arrow indicates the direction of propagation and the red arrow the polarization.

created, as shown in figure 5), where the dimensions of the holes are in the order of magnitude of the wavelength, the influence of silicon substrate becomes more significant, which may explain the higher group velocity of the pseudo-Rayleigh wave in the y direction (Rayleigh wave velocity in silicon being higher). This effect, in the case of the propagation in the x direction, is small compared to that of the folding of the mode (branch flattens) and does not substantially influence the reduction of the velocity in the x direction.

Finally, although the anisotropy was shown to be linked with the holes implemented in the model, the speed decrease of both waves is not explained with this model. It is well known that the GLAD deposition with high angles ($\alpha > 70^\circ$) leads to a voided material, with a given size and shape distribution of the holes [24]. In the simulation model, only the bigger holes (micrometer scaled) were taken into account. However, the smaller holes also have an influence on the wave propagation. Since Biot [30] in 1956, several groups studied the influence of the porosity on the propagation of elastic waves. Former investigations focused on doped porous silicon wafers report that velocities of longitudinal and shear wave (bulk waves) agree with the following power law [31–33]:

$$v = v_0(1 - p)^t \quad (2)$$

with v_0 the velocity of the bulk wave in the homogeneous material (m s^{-1}), p the porosity of the material, and t , an empirical parameter, depending on the nature of the wave, the porosity [33, 34], and the material. It is likely that the porous tungsten deposited by the GLAD technique follows a similar law, which would strongly reduce the velocities obtained in the model presented and thus explain the experimental velocities reductions.

5. Conclusion

In summary, we have performed measurements of the surface acoustic wave propagation in conventional and inclined columnar tungsten thin films by means of a femtosecond heterodyne pump-probe setup. For conventional films, skimming longitudinal and pseudo-Rayleigh waves with a strong dispersion have been observed. The highest surface wave velocity was measured in every direction for these films (more than 3750 m s^{-1}), which is 40% higher than in bulk tungsten and assigned to the contribution of the silicon substrate. The GLAD tungsten films with an inclined columnar microstructure along the x axis exhibit a reduced velocity (-61% and -27% at $k/2\pi = 3 \times 10^5 \text{ m}^{-1}$ following x and y directions, respectively) compared to conventional films. It has mainly been attributed to the porous structure produced by atomic shadowing effect during the film growth. In addition, the inclined columnar tungsten films give rise to anisotropic behaviors of acoustic wave propagation. The highest velocity has been obtained following the direction perpendicular to the column growth (y direction). It was connected to the anisotropic microstructure of the columns. Elliptical cross-sections of the inclined columns develop as the film thickness increases leading to elongated chains on the top, connected to each other and thus, leading to a significant film plane anisotropy. The finite element method was used to simulate the two samples. Simulations implied that the anisotropy is linked to the micrometer scaled holes, whereas the speed reduction is assigned to a nano-porosity inside the columns. Moreover, the anisotropy was connected to the holes geometry, especially their form factor and the choice of the period, the column tilt having only a limited influence. The work presented here substantiates the prospect of creating porous and anisotropic architectures in GLAD thin films as a key feature for an integration in devices such as MEMS, NEMS, sensors or actuators requiring structural and thus anisotropic properties.

Acknowledgments

This work was supported by the Region of Franche-Comté, the French RENATECH network and performed in cooperation with the Labex ACTION program (contract ANR-11-LABX-01-01). This research was also sponsored by the French National Agency for Research (ANR) funds through the PHEMTO project. The authors also thank the BQR ENSMM for financial support through the COSET project.
