\section*{ABSTRACT}

The delay in arrival times between high and low energy photons from cosmic sources can be used to test the violation of the Lorentz invariance (LIV), predicted by some quantum gravity theories, and to constrain its characteristic energy scale $E_{\text{QG}}$ that is of the order of the Planck energy. Gamma-ray bursts (GRBs) and blazars are ideal for this purpose thanks to their broad spectral energy distribution and cosmological distances: at first order approximation, the constraints on $E_{\text{QG}}$ are proportional to the photon energy separation and the distance of the source. However, the LIV tiny contribution to the total time delay can be dominated by intrinsic delays related to the physics of the sources: long GRBs typically show a delay between high and low energy photons related to their spectral evolution (spectral lag). Short GRBs have null intrinsic spectral lags and are therefore an ideal tool to measure any LIV effect. We considered a sample of 15 short GRBs with known redshift observed by Swift and we estimate a limit on $E_{\text{QG}} \geq 1.5 \times 10^{19}$ GeV. Our estimate represents an improvement with respect to the limit obtained with a larger (double) sample of long GRBs and is more robust than the estimates on single events because it accounts for the intrinsic delay in a statistical sense.

\textbf{Key words.} gamma-ray burst: general

\section*{1. Introduction}

A quantum theory of gravity is expected to reconcile the classical theory of gravity and quantum physics. An unanimous quantum theory of gravity does not, however, exist yet. In general such theories predict the existence of a natural scale at which Einstein’s classical theory breaks down. This is the quantum gravity energy scale $E_{\text{QG}}$, expected to be of the order of the Planck energy $E_p = (\hbar c^3/G)^{1/2} \sim 1.22 \times 10^{19}$ GeV. Some approaches to quantum gravity predict a deformation of the dispersion law of photons, $(\epsilon p)^2 = E^2 [1 + f(E/E_{\text{QG}})]$, where $p$ is the photon momentum and $c$ is the velocity of light, that would lead to energy-dependent velocities for massless particles (Amelino-Camelia et al. 1998; Mattingly 2005). At smaller energies, a series expansion can be applicable, that at first order would lead to an energy-dependent photon velocity $v$ of the form:

$$v \approx c \left(1 - \xi \frac{E}{E_{\text{QG}}} \right),$$

where $\xi = \pm 1$ is a sign ambiguity that can be fixed in a specific quantum gravity theory. In what follows we assume that the sign of the effect does not depend on the photon polarisation, that is, the velocities of all photons of the same energy are either increased or decreased by the same exact amount. The dependence of $\xi$ on the polarisation produces a frequency-dependent rotation of the polarisation vector in linearly polarised light, known as vacuum birefringence (Mattingly 2005).

An energy-dependent speed of photons would imply that two photons emitted simultaneously with energies $E_1$ and $E_2$ traveling a distance $L$ accumulate a delay $\Delta_{\text{QG}}$:

$$\Delta_{\text{QG}} \approx \xi \frac{(E_2 - E_1)}{E_{\text{QG}}} \frac{L}{c} \sim 10^{-2} \left(\frac{E_p}{E_{\text{QG}}}\right) \left(\frac{E_2 - E_1}{\text{MeV}}\right) \left(\frac{L}{\text{Mpc}}\right) \text{ms}. \quad (2)$$

There are two ways to magnify this delay in order to measure it: i) to increase the separation between $E_1$ and $E_2$ and/or ii) search for this effect in sources at cosmological distances.

Gamma-ray bursts (GRBs) are exquisite to this purpose: they are observed at cosmological distances (up to redshift 9.2) and their emission during the prompt phase can span several orders of magnitude in energy. The bright short GRB 051221A has been used to set a stringent constraint to $E_{\text{QG}}$ using Konus-Wind data: $E_{\text{QG}} > 0.1 E_p$ (Rodríguez Martínez et al. 2006; see also Rodríguez Martínez & Piran 2006, for a discussion about the methodology). The Fermi gamma-ray telescope, with its broad energy range (from few keV to several GeV), has enabled us to test possible violations of the Lorentz invariance studying the delays among different energy bands, maximising the energy difference. Abdo et al. (2009b) used the long GRB 08091C and its highest energy detected photon (13.2 GeV) to estimate the maximum delay (16.5 s after the trigger) and in turn to provide a constrain: $E_{\text{QG}} > 0.1 E_p$. For the short GRB 090510, the time delay between the trigger time and the arrival time of one 31 GeV photon was estimated to be 0.86 s. This led Abdo et al. (2009a) to set a stringent limit on $E_{\text{QG}} > 1.2 E_p$. Ghirlanda et al. (2010)
and Vasileiou et al. (2013) obtained even tighter constraints for the same GRB with different assumptions ($E_{\text{QG}} > 6.7 \, E_{\text{p}}$ and $E_{\text{QG}} > 7.6 \, E_{\text{p}}$, respectively). Figure 1 portrays the limits currently derived with GRBs and other extragalactic sources. Measures of GRB polarisation have been used to constrain the vacuum birefringence effect (Fan et al. 2007; Laurent et al. 2011; Toma et al. 2012; Götz et al. 2013, 2014; Lin et al. 2016).

Bolmont et al. (2008) and Ellis et al. (2008) performed a statistical study on samples of long GRBs (L-GRBs) with redshift detected by several instruments (HETE-2, BATSE and Swift), deriving that the energy scale $E_{\text{QG}}>2 \times 10^{53}$ GeV and $E_{\text{QG}}>9 \times 10^{51}$ GeV, respectively (see Fig. 1). Though these limits are less stringent than the ones obtained with single events, this statistical approach helps one in accounting for the spectral lag contribution to estimate the possible delay induced by quantum gravity effects (with the exception of specific GRBs, either long or short, we cannot properly model the contribution of the intrinsic spectral lag to estimate the possible delay induced by quantum gravity effects alone (see however Vasileiou et al. 2013, who accounted for the intrinsic spectral lag in a statistical sense in single sources).

In this paper we have adopted a statistical approach as in Bolmont et al. (2008) and Ellis et al. (2008) to single out properly the source contribution to the delay. At variance with previous studies, we considered the largest possible sample of S-GRBs observed by the Swift/Burst Alert Telescope (BAT; Barthelmy et al. 2005). This sample provides three main advantages: i) the spectral lag of S-GRBs is negligible; ii) the dispersion of the spectral lag of S-GRBs is much smaller than for L-GRBs (Bernardini et al. 2015); iii) the use of a single instrument reduces also the possible systematics that arise when combining data from different instruments (Ellis et al. 2008); iv) Swift/BAT enables us to perform the analysis on the largest available sample of S-GRBs with redshift.

In Sect. 2 we describe the sample selection and the methodology used to derive the time delay. In Sect. 3 we detail the derivation of the limit on the quantum gravity energy scale. In Sect. 4 we discuss our results. Errors are given at 1σ confidence level, unless otherwise stated. We used the cosmological parameters based on full-mission Planck observations (Planck Collaboration XIII 2016).

2. Sample selection and methodology

We selected the Swift GRBs classified as short by the BAT team refined analysis, namely all the GRBs with $T_{90} < 2$ s and those whose Swift/BAT light curve shows a short-duration peak followed by a softer, long-lasting tail (the so-called extended emission, with $T_{90} > 2$ s). We also required that these GRBs have a redshift measurement$^{1}$.

We excluded from our analysis GRB 090426 and GRB 100816A since D’Avanzo et al. (2014) considered them as possible L-GRBs (i.e. they likely have a collapser progenitor, Zhang 2006; Bromberg et al. 2013). We ended up with 21 S-GRBs with redshift. Most of these events and their prompt emission properties are reported in D’Avanzo et al. (2014).

In order to calculate the time delay $\Delta t$ between photons of high and low energy, we exploited the same methodology adopted in Bernardini et al. (2015) for the calculation of the spectral lag, namely:

- we extracted mask-weighted, background-subtracted light curves with the `batmaskwtewt` and `batbinevt` tasks in FTOOLS for two fixed observer frame energy bands (ch1: 50–100 keV and ch2: 150–200 keV) within the energy range of the BAT instrument (–[15–200] keV; Sakamoto et al. 2011);
- we used the discrete cross-correlation function (CCF; Band 1997) to measure the temporal correlation of the two light curves in ch1 and ch2. We calculated the CCF value for a series of time delays over the entire light curve that are multiples of the time resolution of the light curves. The temporal delay of the photons is defined as the global maximum of the CCF. For each GRB we tried different time resolutions and we used the minimum one with a chance probability $<10^{-3}$ of finding the corresponding CCF$_{\text{max}}$ to discard statistical fluctuations;
- to locate the global maximum, we fitted an asymmetric Gaussian model to the CCF. This allows us to estimate lags which can be a fraction of the time resolution of the light curves extracted from the BAT data. The uncertainties on the CCF and on the time delay have been derived by applying

---

$^{1}$ We excluded GRB 080905A whose redshift has been questioned in D’Avanzo et al. (2014).

3. Limits to the quantum-gravity energy scale from S-GRBs

The temporal delay between high and low energy photons can be written as

\[ \Delta t = \tau + \Delta t_{QG} \]  

where \( \tau \) is the contribution to the delay intrinsic to the GRB (the intrinsic spectral lag), while \( \Delta t_{QG} \) is the systematic delay induced by the violation of Lorentz invariance. The second term corresponds to the delay in arrival time of two photons with energy difference \( \Delta E \) in the observer frame, emitted simultaneously by a cosmological source located at redshift \( z \) (see Jacob & Piran 2008, for a complete derivation of this formula):

\[ \Delta t_{QG} = \frac{H_0}{E_{QG}} \int_0^\infty \frac{(1+z')dz'}{h(z')} \int_0^\infty (1+z')dz', \]  

where \( H_0 \) is the Hubble expansion rate and \( h(z') = \sqrt{\Omega_\Lambda + \Omega_m(1+z')} \). For convenience, we rewrite Eq. (4) in terms of the time delay measured in the source rest frame:

\[ \Delta t_{QG} = \frac{\Delta t_{QG}}{(1+z)} = \frac{H_0}{E_{QG}} \left[ \int_0^\infty (1+z')dz' \right] \frac{1}{h(z')} \int_0^\infty (1+z')dz'. \]  

Overall, the time delay can be written as a linear function:

\[ \Delta t = q_s + m_{QG}K(z), \]

where \( K(z) \) contains the dependence of the temporal delay upon the distance (the quantity in square brackets in Eq. (5)) and \( q_s = \tau/(1+z) \).

We computed for each S-GRB of our sample the corresponding \( K(z) \) (see Table 1) and fitted to the data the model in Eq. (6) to derive the coefficient \( m_{QG} \). The intercept \( q_s = \tau/(1+z) \) represents the contribution from the intrinsic spectral lag. The rest-frame temporal delay as a function of \( K(z) \) is portrayed in Fig. 2. We considered an extra-scatter \( \sigma_q \) that accounts for the dispersion of the intrinsic spectral lag. Markov chain Monte Carlo techniques are used in our calculations in order to derive the best-fitting parameters: for each Markov chain, we generated 10^4 samples according to the likelihood function. Then we derived coefficients and confidence intervals according to the statistical results of the samples.

In our analysis we used JAGS (Just Another Gibbs Sampler). It is a programme for analysis of Bayesian hierarchical models using Markov chain Monte Carlo simulation. More information can be found: http://mcmc-jags.sourceforge.net/
This yields: $\Delta t_d = (0.95^{+1.20}_{-1.74}) \text{ ms} + [(0.11^{+1.54}_{-0.74}) \text{ ms}] K(z)$. The intrinsic scatter is $\sigma_i = (4.18^{+3.11}_{-2.30}) \text{ ms}$.

The coefficient $m_{QG}$ is consistent with it being zero within 1σ. This allows us to place a lower limit to the effective energy scale for the rising of the quantum-gravity effect, adopting the same technique described above to derive the best-fitting parameters and considering as a prior that the energy is a positive quantity: $E_{QG} > 1.48 \times 10^{16} \text{ GeV (95% c.l.)}$.

4. Discussion and conclusions

The systematic analysis of the temporal lag for S-GRBs observed by Swift allowed us to derive a lower limit for the effective energy scale for the onset of the quantum-gravity delay. Our result is more stringent than those obtained with larger samples of L-GRBs, and is more robust than the estimates on single events because:

- The physical origin of the intrinsic spectral lag is still unclear, and it is not possible to predict theoretically its value for specific events. Furthermore, the intrinsic lag may be negligible, positive or negative without any apparent relation with the GRB properties (Ukwatta et al. 2012; Bernardini et al. 2015), thus it is hard to disentangle its contribution from the purely quantum-gravity delay of photons. Vasileiou et al. (2013) made an attempt to account for intrinsic effects on single bright GRBs observed at GeV energies, finding strong constraints ($E_{QG} > 1.8 E_p$ on S-GRB 090510). However, using a sample of GRBs characterised by a short single event is the best way to account for the intrinsic lag in a statistical sense (see also Bolmont et al. 2008; and Ellis et al. 2008).

- S-GRBs have intrinsic lag consistent with zero, with much smaller dispersion compared to L-GRBs (Bernardini et al. 2015). Thus, using S-GRBs we reduce the uncertainties about the intrinsic lag and its scatter, allowing us to derive more robust constraints than in similar analysis with L-GRBs, though the sample is limited in number. Adding L-GRBs with negligible intrinsic lag would not improve our estimates because though the two samples are likely drawn from the same population (Bernardini et al. 2015), the dispersion for L-GRBs with null lag is much larger ($\sigma_{QG-GRB} = (110 \pm 32) \text{ ms}$). The selection of events observed by a single instrument reduces also the possible systematics that arise when combining data from different instruments (Ellis et al. 2008).

- The intrinsic spectral lag within a single GRB may evolve with time, and the time-integrated quantity parametrised by $q_z$ is only an “average” (in a non-statistical sense) representation of it. Uncertainties much larger than the temporal resolution of the light curves on the lag may be related to the convolution of multiple peaks in the CCF that spread the absolute maximum (Bernardini et al. 2015). This effect is much more relevant for L-GRBs than for S-GRBs.

- S-GRBs have usually lower redshifts than long GRBs (see e.g. D’Avanzo et al. 2014). The average redshift for L-GRBs is $\sim 1.8$, Salvaterra et al. 2012; extending up to $z \sim 9$, Cucchiara et al. 2011). However, the term $K(z)$ weakly increases for large redshifts (~10% when passing from redshift 2 to redshift 4). Therefore, the low redshift range covered by short GRBs does not disfavour their use to probe LIV.

To evaluate if the present result is strongly dependent on the size of the sample considered, we performed a Monte Carlo simulation to evaluate how the constraint improves with the sample size. Starting from our 15 S-GRBs, we added S-GRBs extracted randomly from the population synthesis code for S-GRBs (Ghirlanda et al. 2016), generating an hybrid sample of 15 + 45 S-GRBs. We assigned to each synthetic S-GRBs a lag randomly extracted from the distribution of the 15 real events. The error on the lag depends on the binning size that, in turn, is chosen to have an appropriate signal to noise ratio for the lag computation. This implies that the smaller errors are for brighter bursts. For this reason, the errors on the lags are estimated from an empirical relation with the peak flux derived for the GRBs of our sample ($\log[c\sigma_\text{lag}/\text{ms}] = 2.5 - 0.9 \log[q \phi_{\text{peak}}/(\text{ph/cm}^2/\text{s})]$). This sample has been analysed with the same procedure described above deriving a limit on $E_{QG}$. This Monte Carlo procedure has been repeated $10^5$ times averaging the corresponding $E_{QG}$ estimate. We obtained an improvement of at most a factor of two in the estimate of $E_{QG}$.

Independently of sample size, a sample of events with a widest redshift range can provide better constraints on the $E_{QG}$ value (see Eq. (2)). The sample considered in this paper extends up to $z = 2.2$ (Selsing et al. 2017). Based on the S-GRB redshift distribution reported in D’Avanzo et al. (2014) and Ghirlanda et al. (2016), we expect 5–30% of the Swift S-GRB to have $z > 2$. Considering the Swift S-GRB detection rate (~8 yr$^{-1}$) and the efficiency in measuring their redshift (almost 3/4 of the Swift S-GRB is missing a secure redshift measurement), this translates into about one to six events with measured $z > 2$ over ten further years of Swift activity.

In light of the above considerations, better perspectives to derive more stringent limits with S-GRBs, with all the advantages described above, could rely on the extension of the calculation of the time delay to higher energies, exploiting the GRB broad spectral energy distribution. The method proposed in this paper applied to GeV photons (i.e. a factor $10^5$ in the $(E_2 - E_1)$ term of Eq. (2)) would give a substantial improvement in the constraint. However, there is only one S-GRBs with known redshift and GeV detection by Fermi/LAT (GRB 090510).
