Superimposed images ; image mixture ; image separation ; spatial shift ; sub-pixel motion

Abstract

The problem of the separation of superimposed images is considered in the particular case of a steady background, and a foreground that is composed of different patterns separated in space, and each with a compact support. Each pattern of the foreground may move in time independently. A single pair of these superimposed images is assumed to be available, and the displacement amplitude is typically smaller than the pixel size. Further assuming that the background is smoothly varying in space, an original algorithm is proposed. To illustrate the performance of the method, a real test case of X-ray tomographic radiographs with moving patterns due to dust particles or surface scratches of optical elements along the beam is considered. Finally an automatic and simple treatment is proposed to erase the effect of such features.

1. Introduction

X-ray computed tomography (CT) is an imaging technique that provides a 3D image of a specimen from a set of 2D radiographs acquired while rotating it between an
X-ray beam and a detector. The reduction in beam intensity at a specific detector site is related to the integral of the local attenuation coefficient along the ray (the line parallel to the beam) passing through that site (i.e., the Beer Lambert law). Hence, the radiographs have to be normalized by the incident beam intensity, called “flat-fields”, i.e. radiographs that would be obtained without specimen along the line. One practical source of difficulty (Weitkamp et al., 2011) is that the beam intensity displays temporal variations, and spatial inhomogeneities, especially at synchrotron facilities (Flot et al., 2010) (as shown figure 1(a) on a raw radiograph). Possibly scratches or dust particles along the beam pathway (optics, monochromator, scintillator, mirror, camera) may become visible on the radiographs. They also appear in the flat-fields acquired before and after the experiment (figure 1(b)). Would those defects remain ideally still with respect to the acquisition then they would have no consequence in reconstructions. However, it is observed that some localized patterns move with respect to the background (figure 1(c)). Although their displacements are small, they are very salient and hence may cause artifacts. Moreover, even if in some cases these moving patterns on the radiographs may not be detected after the reconstruction algorithm, they would still introduce bias for qualitative analyses based on the radiographs (Leclerc et al., 2015). Such a real experimental case where such a differential pattern motion takes place will be discussed below, and it will be used in Section 4 to validate our procedure.

The separation of image superimpositions with motion into separate layers has received much attention in past years. Many papers deal with the segmentation and recognition of moving patterns (for video surveillance, pattern recognition, etc) (Kameda & Minoh, 1996; Lipton et al., 1998; Rogers et al., 2007; Ng & Delp, 2010). They consist of segmenting a moving image with respect to a fixed background.

The proposed procedures often make use of the image difference to separate the
different layers. Because moving objects are not transparent and mask the scene, large displacements are often considered so that once the front object shape has been delineated, foreground and background layers may be separated with binary masks.

Transparent image mixtures with motion are more challenging. Such cases occur for example for moving shadows, X-ray images, superimposed semi-transparent objects, partial reflection onto a transparent surface, etc (Irani & Peleg, 1993; Bergen et al., 1990; Auvray et al., 2006). With transparent images, (Be’Ery & Yeredor, 2008; Gai et al., 2008; Gai et al., 2012) proposed a separation method based on the inter-correlation of the image mixture (image gradients may be considered to enhance the signal). Remarkable successes have been reported in terms of separation, however, it is to be noted that such results require specific conditions for the algorithm to be applicable: images have to be uncorrelated, gradients have to be sparse and with a similar weight, the displacement has to be larger than the correlation length in order to properly separate correlation peaks. In particular this technique cannot address cases where the displacement is subpixel. Other works aim to separate the background and foreground for a known displacement field (Toro et al., 2003; Marcia et al., 2008a; Marcia et al., 2008b) and a wavelet decomposition for the two last papers. Again, such methods are not suited to deal with very small displacements. Thus in spite of the variety of the above cited problems and algorithms, none appears
suited to very small displacements such as those encountered in practice for flat-field corrections in Computed Tomography.

A. Ramirez-Manzanares et al. (Ramírez-Manzanares et al., 2007; Ramirez-Manzanares et al., 2010; Ramírez-Manzanares et al., 2011) proposed a method to estimate the displacement field of superimposed transparent images subjected to a small motion. This procedure is based on a variational model for integrating local motion estimations to obtain a multi-valued velocity field. Similar methods were proposed by (Stuke et al., 2004). However, these procedures assume that some tens of images are available in between which the velocity is steady. When reduced to a single pair of images, the problem becomes ill-posed and additional assumptions are to be formulated and exploited.

The goal of the present study is to erase moving particles on fixed X-ray transparent images by developing a robust method to separate a small set of superimposed images (i.e. from two different flat-fields) composed of an extended fixed background (with low and high spatial frequencies) and a localized moving foreground (spatial medium frequencies) with the specificity of handling very small unknown displacement amplitudes (sub-pixel displacement). After having defined our notations in Section 2, the method to extract the displacement, the background and the foreground with a spatial frequency separation is presented in Section 3. Then, in Section 4, the procedure is tested on two X-ray scans. Finally, the correction of other images of the same set and with the extracted results is proposed in Section 5.

2. Statement of the problem and notations

2.1. Images

A digital image is a collection of gray level values \( \hat{f}_i \) for each pixel \( i \) whose centre is at position \( r_i \) of integer coordinates. Although discrete, it may be seen as the
sampling at integer positions, \( r_i \) of an underlying function, \( f(r) \) defined for arbitrary real coordinates \( r = (x, y) \) in a domain \( \Omega \).

Because only \( \hat{f} \) is known and not \( f \), an interpolation scheme is proposed to compute an approximation of \( f \) at any arbitrary point from the knowledge of \( \hat{f} \) (or \( f \) at pixel coordinates). Different interpolants with different degrees of regularity can be proposed to extend \( \hat{f} \) to the continuum. The interpolation scheme relies on a kernel \( h(r) \) defined in the continuum, valued 1 at the origin, and 0 at all other integer coordinate points, so that

\[
f(r) = \sum_{i \in I} h(r - r_i) \hat{f}_i
\]

(1)

where the sum runs over the set \( I \) of all pixels in the image, *i.e.*, pixel centres, and hence for all pixels \( r_i \), \( f(r_i) = \hat{f}_i \).

Registration of two images captured after a translation of small amplitude can provide estimates of the displacement amplitude with an uncertainty well below \( 10^{-2} \) pixel size (down to \( 10^{-3} \) pixel size in favorable conditions, as widely documented in the literature (see e.g. (Schreier et al., 2009))).

Although, this may appear as paradoxical, this property rests on the ability to propose a subpixel interpolation scheme for images that is more accurate than what can be detected by the noise level of the image. It is noteworthy to add that this property is of statistical nature, and results from average properties over large zones of interest. As their size is reduced, displacement uncertainties increase significantly.

Because \( f \) can be deduced from \( \hat{f} \) and vice-versa, no difference is made in the following between the discrete image and its extension to the continuum. In a similar spirit, a \( C^1 \) interpolation scheme (or higher) allows a gradient to be defined, that will be used freely in the following.
2.2. Definition of the problem

An image $f_0(r)$ with Cartesian coordinates $r$ is assumed to be the superimposition of a background $\varphi(r)$ and a localized pattern $\psi(r)$ having a compact support (e.g., a dust particle or a surface scratch of a transparent object encountered along the beam)

$$f_0(r) = \varphi(r) + \psi(r)$$

(2)

In addition to $f_0$, a second image is available where the background remains steady, but the localized pattern is translated by some unknown displacement both in orientation and magnitude. The latter will be assumed to be small in the following

$$f_1(r) = \varphi(r) + \psi(r + u_1)$$

(3)

Moreover, over the entire image, $u_1$ is assumed to be uniform (i.e., independent of $r$). The two images, $f_n$, for $n = 0, 1$, are known but $\varphi$ and $\psi$ are not. Similarly, the displacements $u_1$ is not known, one can conventionally choose $u_0 = 0$.

The fact that the moving object is a localized pattern with compact support means that $\psi(r) = 0$ away from a region that can be easily circumscribed. Let us note that one may not only encounter X-ray absorption, but also phase contrast effects that redirect the beam locally. Hence one may observe an increase of intensity and not only an attenuation so that a positivity constraint on $\psi$ is not considered. It is also necessary to mention some further property of the background $\varphi$. The latter displays both long wavelength modulation and high frequency noise. However, it is assumed to be statistically stationary. In other words, if $\psi$ is subtracted from say $f_n$, the prior localization of $\psi$ should not be visible in $\varphi$. This is to be contrasted with $f_n$ where the presence of a specific pattern is manifest.
3. Method

3.1. Ill-posed problem

Without additional assumptions on $\varphi$ and $\psi$ the problem is ill-posed, in the sense that its solution is not unique, as shown below.

Let us note that the differences between two frames

$$d_1(r) \equiv f_1(r) - f_0(r) = \psi(r + u_1) - \psi(r)$$

only depends on $\psi$ and no longer on $\varphi$. To simplify the notations, for difference, $d$, and displacement vector, $u$, the subscript $n$ or 1 is dropped.

The pattern $\psi$ appears to be determined from its finite difference if $u$ is known. Assuming that $\psi$ is null over a strip of width $u$, integration is straightforward and leads to a particular solution to Eq. (4). However, any periodic function, of period $u$, can be added to $\psi$. Once $\psi$ is determined, then $\varphi$ is obtained by a mere difference (see Eq. (2)). Therefore, in addition to a constant offset as mentioned in (Szeliski et al., 2000), any periodic function of period $u$, can be added to a particular solution and still fulfills exactly equation (3) for any $f_0$ and $f_1$. Thus, the problem is ill-posed with a large degeneracy.

To make the problem well-posed, some additional constraints have to be prescribed. In our case, the property that $\psi$ is a localized pattern with a compact support provides a simple way to determine the unknown periodic function in order to minimize the power of $\psi$ outside a domain where it is assumed to be non-zero. Thus for any $u$ the degeneracy is reduced to a single solution that achieves the best score in matching the known difference $d$. The remaining question is whether one can determine independently the displacement $u$. 
3.2. Determination of the displacement orientation

Let us consider the Radon transform of \( d, \rho \equiv R[d] \), given by the line sum of \( d \) along parallel lines at an angle \( \theta \), or
\[
\rho(s, \theta) = \int_{C} d(se_{\theta} + \pi/2 + te_{\theta}) \, dt
\]
where \( e_{\theta} \) is a unit vector forming an angle \( \theta \) with the \( x \) axis, and \( C \) denotes a circular disk of radius \( a \) containing the domain where \( d \) is non-zero.

Let us call \( \alpha \) the polar angle of the displacement vector, \( u = ue_{\alpha} \), then
\[
\rho(s, \alpha) = \int_{C} d(se_{\alpha} + \pi/2 + te_{\alpha}) \, dt \\
= \int_{C} \psi(se_{\alpha} + \pi/2 + (t + u)e_{\alpha}) \, dt \\
- \int_{C} \psi(se_{\alpha} + \pi/2 + te_{\alpha}) \, dt \\
= R[\psi](s, \alpha) - R[\psi](s, \alpha) \\
= 0
\]
for all values of \( s \). Thus the \( L_2 \) norm of \( \rho(., \theta), l(\theta) \),
\[
l(\theta)^2 \equiv \int_{-r}^{r} \rho(s, \theta)^2 \, ds
\]
is a positive function that should reach its minimum (ideally 0) in the direction of the motion \( \theta = \alpha \). This property is interesting as it allows the determination of the displacement orientation without any further assumption than the compact support of \( \psi \). In order not to bias this criterion along preferred directions, it is natural to clip the integration domain for the Radon transform and the \( L_2 \) norm to a circular domain centered on the pattern.

3.3. Ill-posedness

Let us note that even if the displacement direction can be inferred, the magnitude itself remains an issue. The problem is still ill-posed as can be easily observed in the limit of a small displacement (a limit that is relevant for our application). Indeed in
such a case, the difference between images can be written

\[
d(r) = \psi(r + u) - \psi(r) \\
\approx |u| \| \nabla \psi(r) \cdot e_\alpha
\]

(8)

Therefore, knowing \(d\) and \(e_\alpha\) gives access to the product of the displacement magnitude by the component of the gradient along the displacement direction, but with this sole argument, it does not allow one to isolate \(|u|\) from \(\nabla \psi \cdot e_\alpha\). Hence the problem remains ill-posed, and the criterion on the compact support of \(\psi\) does not help.

3.4. First step

Let us first propose the partial reconstruction of \(\psi\), from the above observations. Because at this stage, it is not possible to split displacement magnitude and pattern gradient, we propose to compute the pattern for a chosen value of the displacement magnitude, here one pixel. This value is by now conventional and its determination will be discussed later. In order not to introduce any confusion in the latter quantity and \(\psi\), and because it is related to first order integration of \(d\), we call this integral \(D\).

It solves the following equation

\[
d(r) = \nabla D(r) \cdot e_\alpha
\]

(9)

Later, when the displacement magnitude will be known, \(\psi\) will be estimated as

\[
\psi(r) = \frac{D(r)}{|u|}
\]

(10)

3.5. Integration

Although the problem is now well-posed, there are several ways to implement the integration of \(D\) numerically. Let us recall that the displacement \(u\) may be subpixel, or even if its magnitude is one pixel as above chosen, the arbitrary angle \(\alpha\) requires that a subpixel interpolation scheme be available.
Thus, $D(r)$ is chosen under the following form

$$D(r) = \sum_{i \in I} b_i h(r - r_i)$$  \hspace{1cm} (11)

where the index $i$ runs over the set $I$ of all pixels in the image, $r_i$ designates the coordinate of pixel $i$, $b_i$ the unknown amplitudes and $h$ is the elementary shape function relative to a pixel centered at the origin. In the following, the interpolation scheme is inspired from finite-element, with a bilinear interpolation. In this case, the shape function suited to the square lattice of pixels, at any arbitrary real point of coordinates $r = (r_x, r_y)$ is

$$h(r) = (1 - |r_x|)(1 - |r_y|)$$  \hspace{1cm} (12)

if $|r_x| < 1$ and $|r_y| < 1$, and else $h(r) = 0$. It is classically referred to as Q4P1 (4-noded Quadrilateral, Polynomial of order 1).

The determination of $D$ is to be performed from the minimization of

$$\chi^2_1(\{b\}) = \int_C \left( \sum_i b_i (h(r - r_i) - d(r)) - h(r - r_i) \right)^2 dr$$  \hspace{1cm} (13)

If some additional information is available concerning $\psi$, one may choose, instead of a pixel representation, $h$, a basis that is tailored to the expectation. The interest of introducing such a form is that because of noise and subpixel interpolation, the line sum $\rho(s, \alpha)$ is not strictly 0 over the domain (disk) of integration. In this case, the above minimization allows the distribution of the additional weight on both sides of the pattern, whereas a direct integration would lead to a dissymmetric $D$.

3.6. Second step

The criterion to find $|u|$ is to assume that if the object is removed from the background, then no ghost mark (neither positive nor negative) should appear on the “computed” background. However, one difficulty is that this background itself is unknown. As above discussed, for any $u$, one can compute $\psi_u(r)$ (where the subscript recalls
that this pattern estimate depends on \( u \) that remains to be determined). In turn, the background is \( \varphi_u(r) = f_0(r) - \psi_u(r) \).

A spatial frequency separation is performed in the proposed approach. The medium frequencies (5-20 pixels) are considered as moving patterns whereas the low frequencies are related to the background and high frequency (1 pixel) to noise. As a way to estimate the long wavelength modulation of the background over a region \( \Omega \), it is proposed to perform a least square fit weighted by a function \( w(r) \) that is null over the expected support of \( \psi \) and non-zero in its surrounding. A set of slow modulation functions, \( g_i(r) \), with \( i = 1, ..., N_f \), is introduced so that

\[
\varphi_u(r) - \sum_{i=1}^{N_f} a_i g_i(r) = \int_{\Omega} w(r) \left( \varphi_u(r) - \sum_{i=1}^{N_f} a_i g_i(r) \right)^2 dr
\]

(14)

The least-squares solution is obtained from

\[
a_i = M_{ij}^{-1} s_j
\]

(15)

where

\[
M_{ij} = \int_{\Omega} w(r) g_i(r) g_j(r) \, dr
\]

(16)

and

\[
s_i = \int_{\Omega} w(r) g_i(r) \varphi_u(r) \, dr
\]

(17)

It is to be noted that this expression can be rewritten as

\[
a_i = \int_{\Omega} \gamma_i(r) \varphi_u(r) \, dr
\]

(18)

\[
\gamma_i(r) = w(r) M_{ij}^{-1} g_j(r)
\]

and hence the remainder is

\[
\tilde{\varphi}_u(r) = \varphi_u(r) - \left( \int_{\Omega} \gamma_i(r') \varphi_u(r') \, dr' \right) g_i(r)
\]

(19)

\[
= \int_{\Omega} \left[ \delta(r - r') - \gamma_i(r') \varphi_u(r') \right] \varphi_u(r') \, dr'
\]

where the above writing illustrates that \( \tilde{\varphi}_u \) is related to \( \varphi_u \) through a linear operator (projector),

\[
\tilde{\varphi}_u(r) = \int_{\Omega} P(r, r') \varphi_u(r') \, dr'
\]

(20)
where

$$P(r, r') \equiv \delta(r - r') - \gamma_i(r')g_i(r)$$

(21)

The above linear regression is expected to capture the slow modulation of the background and hence for the appropriate value of the displacement magnitude $|u|$, $\bar{\varphi}_u(r)$ should only consist of the white noise. It is therefore proposed to estimate $|u|$ from the minimization of $\chi^2(|u|) = (1/2)\|\bar{\varphi}_u\|^2$.

Using

$$\varphi_u(r) = f_0(r) - \psi_u(r) = f_0(r) - \frac{D(r)}{|u|}$$

(22)

we can write the stationarity condition as

$$\frac{\partial \chi^2(|u|)}{\partial |u|} = \frac{\partial \chi^2(|u|)}{\partial \varphi_u} \frac{\partial \varphi_u}{\partial |u|} = 0$$

(23)

Because the piece-wise linear interpolation of the discrete values of pixels is used, the integration over the domain $\Omega$ can be written as a discrete sum. Hence the previous equation can be expressed in matrix notation

$$\left(f_0 - \frac{D}{|u|}\right)^\top PP^\top \frac{D}{|u|^2} = 0$$

(24)

with $|u|$ a scalar homogeneous displacement, $f_0$ and $D$, vectors composed of the $N_{pix}$ pixels of the integration domain, $^\top$ denotes transposition and where the projection matrix $P$ is of size $[N_{pix} \times N_{pix}]$. Thus, finally, we arrive at the expression of the displacement modulus

$$|u| = \frac{D^\top P^\top PD}{f_0^\top P^\top PD}$$

(25)

The pattern shape can finally be obtained using equation (10), and the background from the difference.

In the case of a large displacement $u$ typically larger than the correlation length or the spot length for a compact image, the linear approximation of equation (8) is
meaningless thus \( d(r) \) cannot be approximated by the derivative of \( \psi \). The displacement can be decomposed into a first guess displacement \( u_0 \) (e.g., obtained from a previous computation in an iterative scheme or a maximum cross-correlation) and a correction \( \delta u \), hence \( u = u_0 + \delta u \). The above procedure can be extended to estimate the displacement correction \( \delta u \). In this case, the problem becomes affine in \( \delta u \) (rather than linear as above discussed) as a result of

\[
d(r) \approx \psi(r + u_0) - \psi(r) + \nabla \psi(r + u_0) \delta u
\]

(26)

4. Case study

4.1. Test case presentation

To illustrate the performance of the proposed method, a real tomographic acquisition performed at the ESRF synchrotron, beamline ID19, is chosen. A nodular graphite cast iron is imaged at a voxel size of 5.1 \( \mu \)m. A complete scan corresponds to 600 radiographs, and flat-fields are recorded before the scan and after every 100 radiographs, resulting in \( N_f = 7 \) flat-fields. The radiographs are denoted as \( I(r, t) \) and the flat-fields as \( f_i(r) \), \( i = 1, ..., N_f \).

The noise is supposed to be white and Gaussian with a standard deviation of 0.24\% as assessed from regions in the images where no mobile patterns are present and thus image difference is assumed to be essentially due to noise.

The flat-field correction procedure with stationary intensity correction has been presented in detail in (Jailin et al., 2017). The principle can be summarized as follows: taking into account the multiplicative nature of the corrections, the logarithm of the radiographs \( G(r, t) = \log(I(r, t)) \), i.e., hereafter called the “projections”, should first be computed and the logarithm of the beam intensity should be subtracted off. The standard Beer Lambert law relates the sum of the absorption coefficient along the ray hitting the detector at position \( r \) and time \( t \) to \( s(r, t) = G(r, t) - F(r, t) \) where
\( F(\mathbf{r}, t) = \log(f(\mathbf{r}, t)) \) and \( f(\mathbf{r}, t) \) is the flat-field at time \( t \). If the beam were steady, \( F(\mathbf{r}, t) \) should be equal to \( F_i(\mathbf{r}) = \log(f_i(\mathbf{r})) \), for all \( i \). However, in the real life, \( F(\mathbf{r}, t) \) varies in time as the X-ray beam is not steady. Since it is not possible to measure simultaneously \( I \) and \( F \), one has to estimate \( F(\mathbf{r}, t) \) from \( F_i(\mathbf{r}) \).

Because the edges of the radiographs (\( \mathbf{r} \in \Omega_l \cup \Omega_r \), defined by the two rectangles shown in figure\[4.1](a)) are never masked by the scanned specimen they provide an information about the intensity variation at all instants \( t \). The two sub-images from the projections clipped to these edge regions at time \( t \) can be approximated as a linear combination of the corresponding sub-images extracted from the (logarithm of the) \( N_f \) flat-fields \( F_i(\mathbf{r}) \) using least squares (some extra fields can be included into this database of all flat-fields (hereafter called library), as will be the case in section\[5] with the addition of a flat-field gradient)

\[
G(\mathbf{r}, t) = F(\mathbf{r}, t) = \sum_{i=1}^{N_f} \beta_i(t) F_i(\mathbf{r})
\]  

(27)

Because the flat-fields are known over the entire detector, the above decomposition allows the extension of the logarithm of the raw beam intensity \( F(\mathbf{r}, t) \) to any \( \mathbf{r} \).

This procedure provides an accurate correction in most of the detector area. Nevertheless a few features remain visible because the radiographs are polluted by moving dust particles or surface scratches of optical elements along the beam.

The flat-fields acquired before and after the experiment and those used for the flat-field library \( F \) are shown in figure\[4.1](a-b). These images are composed of a low
frequency background (i.e. mostly a vertical gradient), a high frequency noise and a few medium frequency bright spots. The difference (c) shows:

- A stationary background composed of low frequencies and a few spots with negative values. The intensity of these spots is different from that of the background and are thus very clearly visible in the difference. However, because of the (logarithm of the) flat-field sampling \( N_f = 7 \) linear combinations can capture those spots and the current procedure of allowing any combination of fields allows us to account for them.

- Other patterns composed of positive and negative values (labeled from 1 to 5). These patterns are moving spots and remain visible in the corrected radiographs. They can be automatically selected by a mere thresholding procedure.

The following study will successively extract the shape of each of these spots, focusing on areas around each moving patterns (figure 4.1(c)) with two images weighted to have a zero-mean value on these regions. The difference of two flat-fields zoomed in the first region is shown figure 4.2. A diverging color bar is used for residual maps to highlight positive and negative patterns. It can be seen that the background disappears and a positive and negative pattern due to the moving spot in a vertical direction remains. The previous procedure can be applied to extract the spot shape of these areas.

4.2. Separation of the two images

The proposed procedure has been first applied on spot 1 (see figure 4.1(c)) and the results for the other spots follow. The extracted area 1 is shown in figure 4.2 for the initial (a) and the final (b) flat-fields.

The first step is to obtain the direction of the displacement by using the Radon transform. The difference image, \( d \), is clipped to a disk \( C \), \( i.e. \), for the surface lying
outside the circle shown in Fig. 4.2 c) is set equal to 0), the Radon transform \( \rho = R[d] \) is computed and the mean quadratic intensity for every angle, \( l(\theta)^2 \), is computed as in Eq. (7). The results are displayed in figure 4.2. The minimum obtained in figure 4.2 b) gives the direction of the displacement: \( \theta \approx 80^\circ \) from the horizontal \( x \)-axis.

Because the background is essentially composed of low frequencies, it can be extracted with the projector \( P \) using low order polynomials (up to second order) \( g_i(r) \). This projection has to be weighted by \( w(r) \) to not be affected by the bright spot shape. The indicator function of the complement to the disk used for the Radon transform was chosen for the studied spot. For elongated marks such as the one labeled “4”, a rectangle was selected.

The computation of \( D(r) \) composed of \( 26 \times 32 \) pixels is regularized by reverting to a square shaped (Q4) mesh composed of \( 10 \times 15 \) nodes. Equation (25) allows the estimation of the displacement amplitude as \( |u| = 0.54 \text{ pix} = 2.72 \text{ \mu m} \). The foreground \( \psi_u \) (Eq. (10)) and finally the background \( \varphi_u \) are evaluated. The \( D(r) \) results linked to the shape of the pattern may be sensitive to the high frequency noise. In our case,
the spot is composed of medium frequencies so the $D(r)$ can be regularized by a finite element mesh composed of a small number of degrees of freedom, (the choice of a mesh based on elements larger than the pixel size leads to a lower sensitivity to noise).

The procedure can be summarized in the following four steps:

- Radon transform for the measurement of the motion direction (equation (7)) to evaluate the direction of motion
- Computation of $D$ and $P$
- Measurement of $|u|$ (equation (25))
- Foreground and Background $\psi_u$ and $\varphi_u$ extraction (equation (10))

The different images, $F$, $\psi_u$ and $\varphi_u$ are shown in figure 4.2.

Results for the four other proposed spots of figure 4.1, $F_1$, $F_1 - F_2$, $\psi_u$ and $\varphi_u$ are shown respectively in figure 4.2 (a,b,c,d) It can be seen that for the fourth pattern, a “ghost mark” still remains on the background but the general shape of the pattern is well captured.

5. Application to automatic flat-field correction

The previous section showed that it is possible to segment each pattern, estimate its shape and intensity as well as its displacement from one image to another one. Yet, this treatment requires a number of manual operations, from the detection of each feature to its analysis. Although feasible, it is a lengthy treatment that appears as affordable
only for exceptionally important data. Thus a key question is whether one can benefit from such an analysis to remove artefacts from tomographic projections at a much lower cost. It turns out that the answer is positive, at least when the displacement range remains small.

The key observation relies on the fact that the absolute shape of the pattern is not strictly needed, nor is the displacement amplitude. Only an estimate of the pattern gradient is necessary, and for the component of the gradient along the translation direction, this is part of flat-field differences. However, because the motion is different for the patterns and the background, it is necessary to limit those differences to the immediate surrounding of the pattern. In fact, the creation of such a binary mask \( \mu(\mathbf{r}) \), valued 1 around each spot and 0 elsewhere is easily performed from standard image analysis techniques as the patterns are isolated salient objects in each flat-field image. Then masked flat-field differences \( (f_i(\mathbf{r}) - f_0(\mathbf{r}))\mu(\mathbf{r}) \) directly contain (i.e. without further treatment) an estimate of the pattern gradient along the direction of motion. Such a field is shown in figure 5. Hence, in the same way as in section 4.1, minimizing the quadratic difference of any projection with a linear combination of flat-fields and in addition of the masked differences, should enable accounting both for the background correction and spurious mobile features. This procedure is in line with the proposed scheme to estimate the raw beam intensity, and turns out to be a very simple extension. In other words, the flat-field gradient has to be added to the flat-field library \( F_i(\mathbf{r}) \).

Note however that this procedure relies on the fact that only the motions sampled by the different flat-fields are generated. When the number of flat-fields is limited to a small number, one may not achieve enough freedom. However, the partition of the mask into different masks (one for each pattern) is an easy way to allow for different motions at different places. Yet, this forces the direction of motion to be aligned with
the one that is sampled. To provide even more freedom, the mask can be applied to each of the two components of a flat-field gradient.

In order to validate the above procedure, it is now applied to the actual test case. The edges of the projections are composed of only two spots: (2) and (5) (see Fig. 4.1). The residual in these regions will obviously be low thus it cannot be considered as a criterion. The criterion to judge if the procedure is accurate is the comparison of another spot not included in the minimization process: the fourth which has the highest intensity value. The gradient field composed of the different extracted pattern gradients is shown figure 5. The result of the flat-field correction around the fourth spot is shown figure 5 for the standard correction (proposed in (Jailin et al., 2017)) (a) (i.e. with a library composed of two flat-fields) and the presently proposed correction with the gradient field (b).

Because the standard procedure is weighted by the global intensity variations, it
does not totally take into account the moving patterns. With the actual procedure, the
displacement amplitude is obtained with the two moving spots on the edges and then
used to correct the central area (and hence the other spots including the above shown
fourth one). The low and uniform residual with the proposed method shows that the
separated pattern shape is well estimated. The obtained displacement amplitude $|u|$ is 0.42 pix. and, because the previous analysis has been carried out, one can estimate
the motion of spot 1 to about 1.15 µm.

Although the initial motivation was based on the reduction of artefacts in recon-
structed images, the present procedure — albeit successful — turns out not to display
an appreciable benefit. The main reason comes from the fact that a spurious static
feature in the radiographs (if away from the projection of the rotation axis) is smeared
over half or a complete ring in the reconstructed volume and becomes difficult to dis-
tinguish. One may note that this tolerance to local bias is one of the reason for the
tremendous success of tomographic reconstruction. Even when algebraic reconstruc-
tion techniques are used, the improvement due to the erasing of the mobile patterns
is difficult to evidence. Although the difference in the reconstructed fields with or
without mobile pattern removal clearly shows the impact of the preprocessing, finding
objective measurements to decide on the best reconstruction is subtle. Attempts made
with entropy evaluation showed at most a 1% difference, a level than can hardly be
considered as meaningful.

However, it has recently been proposed to track the time evolution of a deformable
3D object from a prior full tomographic reconstruction and the inspection of only a
few of its projections at later times (Leclerc et al., 2015; Taillandier-Thomas et al.,
2016a; Taillandier-Thomas et al., 2016b). Such algorithms are much less resilient to
inaccurate or unfaithful projections, as just a few of them are used to extract all
the needed information about sample motion. For such demanding applications, the
proposed treatment is expected to be much more beneficial.

6. Conclusion

The separation of a slowly varying background and a localized pattern is addressed in the difficult case of subpixel motion. Although the general problem is ill-posed, using assumptions on the compact support of one image and a smoothly varying background, a methodology is proposed to achieve the partition and to estimate the motion in orientation and magnitude.

The proposed algorithm was tested on a set of flat-fields acquired on a synchrotron beamline. Five different features were analyzed independently, and revealed subpixel translations. Based on this result, a very simple and generic treatment is proposed to correct for such artefacts prior to reconstruction. The proposed methodology reduces to the construction of a masked image difference as an enrichment of a library built to account for inhomogeneous beam intensity.

**Synopsis**

This paper proposes a separation method for images composed of the superposition of a steady background and several foreground patterns with different sub-pixel motion. The application to the correction of X-ray radiographs allows the erase of moving particles that pollute the reconstruction.
