Micro- or nano-structuring is essential in order to use Si as an anode material for lithium ion batteries. In the present study, we attempted to use Si wafers with a spiky microstructure (SMS), the so-called black-Si, prepared by a cryogenic reactive ion etching process with an SF_6/O_2 gas mixture, for Li half-cells. The SMS with various sizes of spikes from $2.0\text{ }\mu\text{m}$ (height) $\times$ $0.2\text{ }\mu\text{m}$ (width) to $21\text{ }\mu\text{m} \times 1.0\text{ }\mu\text{m}$ was etched by varying the SF_6/O_2 gas flow ratio. An anode of SMS of $11\text{ }\mu\text{m}$ -height in average showed stable charge/discharge capacity and Coulombic efficiency higher than 99% for more than 300 cycles, causing no destruction to any part of the Si wafer. The spiky structure turned columnar after cycles, suggesting graded lithiation levels along the length. The present results suggest a strategy to utilize a wafer-based Si material for an anode of a lithium ion battery durable against repetitive lithiation/delithiation cycles. *Published by AIP Publishing.*

I. INTRODUCTION

For lithium-ion batteries (LIBs) of next-generation, researches to seek alternative anode materials that would be superior to graphite carbon (theoretical gravimetric specific capacity $C_{\text{m-th}} = 372\text{ mA h g}^{-1}$) are ongoing.^{1–9} Among the materials with near-zero potential according to Li/Li^+ , silicon (Si) is one of the most attractive candidates because of its huge $C_{\text{m-th}}$, 4200 mA h g^{-1} for $\text{Li}_{22}\text{Si}_5$ (Ref. 3) or 3579 mA h g^{-1} for $\text{Li}_{15}\text{Si}_4$ (Ref. 10). This huge capacity, however, implies at the same time that significant volume expansion occurs on Si during lithiation (+300% from Si to $\text{Li}_{22}\text{Si}_5$).^{2,11} A low diffusion coefficient of Li ions in Si causes selective Li alloying at the surface of the Si material, and thus different volume expansion between the surface and bulk regions, which leads to cracking or pulverization of the bulk Si material, making the anode fragile and non-durable.^{3,4} Furthermore, this process could lead to a continuous destruction of the solid electrolyte interphase (SEI) layer during the electrode cycling, causing capacity loss (cumulative irreversible capacity). In order to avoid these problems, nanostructured Si materials including nanoparticles,¹² nanowires,^{1,13,14} nanotubes,³ and thin films¹⁵ have been attempted for their utilization as anodes in LIBs. The critical size of Si nanowires as anodes of LIBs for being free from destruction was reported to be $\sim 70\text{ nm}$ (Ref. 16) or $\sim 100\text{ nm}$ (Ref. 14).

Here, considering the four-fold volume expansion from pure Si to alloyed $\text{Li}_{22}\text{Si}_5$, the ideal design of the anode would be such that the final alloy fills the volume of the electrode space, i.e., the initial Si material occupies a quarter of the layer in volume. From this viewpoint, we are focusing on Si nano- or micro-structures prepared by etching Si wafers rather

than by growing nanowires or nanotubes. We have chosen two types of etched Si wafers, wet-etched porous Si and dry-etched microstructured Si. Concerning the former type of wafers, prepared by electrochemical etching in a hydrofluoric acid (HF)-based liquid electrolyte, we have reported that a macroporous Si layer (with pores of $5\text{--}8\text{ }\mu\text{m}$ in diameter and $17\text{ }\mu\text{m}$ in depth) transplanted onto a copper foil acts as a flexible negative electrode. This anode showed stable cycling performance with a gravimetric specific capacity, C_{m} , of 1360 mA h g^{-1} , under conditions of a voltage scan range of $0.125\text{--}0.7\text{ V}$ and a current density of $C/20$.¹⁷ We have also reported that a mesoporous Si wafer (with pores of $60\text{--}70\text{ nm}$ in diameter, $5\text{ }\mu\text{m}$ in depth) achieved a higher C_{m} of 2480 mA h g^{-1} (under $0.07\text{--}2\text{ V}$, $C/9$) and 1910 mA h g^{-1} (under $0.1\text{--}2\text{ V}$, $C/9$) being accompanied by a capacity retention of 97% for 70 cycles in the latter case.¹⁸ The advantages of electrochemical etching processes include low cost in production and reproducibility of well-defined porous structures. Yet, neither of our previous works nor the ones by other groups has achieved a wafer-based Si anode that is free from fading against hundreds of cycling processes. In the case of a LIB prepared on a Si wafer, a diffusion barrier layer is generally inserted between the anode part and the base wafer.¹¹ A wafer-based Si nanowire anode, prepared by means of a silver nanoparticle-assisted electroless chemical etching process, has been reported with their cycling properties, however, for no more than ten cycles and with current-potential profiles that are more or less inconsistent with other Si anodes.¹⁹ If a well-cyclable wafer-based Si anode would be realized without a barrier layer, it could be an elemental technology for embedding a LIB into a CMOS device chip.

The latter type of etched Si, prepared by a cryogenic SF_6/O_2 ion etching process,²⁰ is also interesting for

application as an anode of LIBs. By exposing a blank silicon surface cooled at a cryogenic temperature to a SF_6/O_2 plasma, one can achieve a microstructure that consists of spikes or needles with tall pyramid-like outlines and graded widths that increase from the surface to the bottom,²¹ in contrast to electrochemically etched porous Si structures with a constant width. Si wafers with such microstructures, the so-called black-Si, have been mainly applied for solar cells, thanks to their function of antireflection.²² A trial of using black-Si as the anode of LIBs has already been reported by Lee *et al.*, with a huge initial specific capacity, but an early decline of the specific capacity in charge/discharge cycling.⁹ In the present study, we adopted black-Si consisting of pyramid-like spikes as the anode material of Li half-cells and examined their charge/discharge properties. The results revealed that the half-cells using black-Si anodes with certain sizes of the spiky microstructure (SMS), even with the bulk Si wafer under it, showed excellent cyclability.

II. EXPERIMENTAL

SMS were prepared on 0.5 mm-thick, n-type Si (100) wafers with a resistivity of $\sim 10 \Omega \text{ cm}$ by means of a cryogenic deep reactive ion etching (DRIE) process in an inductively coupled plasma (ICP) reactor (Alcatel, 601E) using a mixture of SF_6 and O_2 gases.²³ The wafer chuck was cooled by liquid nitrogen. The etching was performed under fixed conditions such as a source power of 1000 W, a self-bias voltage of -40 V , an SF_6 flow rate of 200 sccm, a total pressure of 3 Pa, a sample temperature of -130°C , and an etching duration of 10 min. Only the O_2 flow rate was varied among the samples from 20 to 40 sccm, so that the SF_6/O_2 gas flow ratio was controlled (hereafter, we label the SMS Si sample prepared with the O_2 flow of xx sccm as SMSxx). The cross sections and top view images of etched Si wafers were observed with a scanning electron microscope (SEM; Zeiss, Supra 40).

Electrochemical half-cells, each of which is based on a SMSxx chip (xx = 20, 25, 30, 35, 40) as a working electrode and a piece of Li foil (Sigma Aldrich) as both reference and counter electrodes, were prepared in an argon-filled glove-box (with water and oxygen levels below 10 ppm) within the form of two-electrode 2032-type coin cells. Before introduction, the SMS Si chips, cut from the wafer, were slightly etched in diluted HF, and their back surface was coated with titanium (Ti) by a dc sputtering deposition method. The etching in HF was necessary; otherwise, no circuit current occurred in the half-cells, apparently due to a remaining passivation layer SiO_xF_y that had been formed on the surface of SMS during the plasma process.⁹ The Ti coating is also for obtaining good electrical contact between the Si wafer and the coin cell part. The electrodes were separated by the pair of a polypropylene membrane (Celgard, 2400) and a glass microfiber membrane (Whatman, GF/C) impregnated with a liquid electrolyte, which was 1 M LiPF_6 dissolved in a 1:1:3 mixture of ethylene carbonate (EC), propylene carbonate (PC), and dimethyl carbonate (DMC). The Li foil piece, circular with a diameter of 10 mm, was put on the membrane so as to cover the area of the SMS chip.

Electrochemical measurements were carried out for all the half-cells of SMSxx with a versatile multi potentiostat (Biologic, VMP3). Galvanostatic charge/discharge cycling was performed at different charge limits (Q_L) and current densities (J_a). The maximum Q_L value was set to be around 75% of the theoretical capacity calculated from $C_{m\text{-th}}$ (3579 mA h g^{-1}) and areal density M (mass per area) of the SMS layer. Here, M was roughly estimated by performing binary processing onto a top-view SEM image of the sample to deduce the nominal areal occupancy of spikes, which was then multiplied by the averaged height of spikes and the density of Si (2.33 g cm^{-3}). The charge steps were terminated with respect to the charge limit Q_L , whereas the discharge steps were terminated by the higher potential limit, 1.2 V vs. Li/Li^+ . Note that the lower potential limit was also set at 0.02 V, which was actually never reached during the cycling. After selected discharge processes, electrochemical impedance measurements were performed under open circuit potential between 1 MHz and 10 mHz with a signal amplitude of 7 mV. Si anodes were taken out from the cells after charge/discharge cycles and washed with DMC in the glove-box to capture post-mortem SEM images (Zeiss, ULTRA Plus).

III. RESULTS AND DISCUSSION

Sizes of the SMS strikingly depended on the SF_6/O_2 ratio, as summarized in Fig. 1(a). A smaller O_2 flow resulted in longer spikes, even for the same etching duration of 10 min. Note that the length (height) of the spikes does not correspond to the depth of etching, as explained later. The averaged length of the spikes ranged from $21 \mu\text{m}$ in SMS20 to $2.1 \mu\text{m}$ in SMS40, and the averaged width from $1.0 \mu\text{m}$ to $0.22 \mu\text{m}$. The process of spike formation is schematically explained in Fig. 1(b). As the etching advanced, the merging of neighboring pores [Fig. 1(b-ii)] results in a pointed spike with a pyramid-like “frame structure” having its top underneath the initial wafer surface [Fig. 1(b-iii)]. The pyramid-like frame structure implies a graded thickness of the Si walls, thinner at the top and thicker at the base. The structure difference between our black-Si and Lee’s one, with cylinders and no thin walls,⁹ originates in the different processes, which in the latter case consists of alternate etching/depositing steps with SF_6 and C_4F_8 gases, respectively (Bosch process). Figures 1(c) and 1(d) show cross-sectional and top-view SEM images, respectively, of SMS25. One can easily find Si walls with the local thickness thinner than 100 nm in Fig. 1(d).

Here, we show the results of electrochemical characterization on a Li-ion half-cell with a chip of SMS25 (with the averaged height and width of $11 \mu\text{m}$ and $0.75 \mu\text{m}$, respectively, and an area of 36 mm^2) as a representative. Figure 2(a) shows the charge/discharge curves for the first 5 cycles of galvanostatic cycling. In the 1st cycle, a rapid decrease of the potential from the open circuit voltage of the electrode (2.4 V) to $\sim 90 \text{ mV}$ was observed. As expected, the Si-Li alloying reaction was confirmed in a potential region below 0.5 V.^{1,10,24–26} Then, the charging continued until the capacity limit, $112 \mu\text{A h cm}^{-2}$, with the potential staying in a

FIG. 1. (a) Averaged height and width of spikes in various SMS samples. Error bars represent the scattering of sizes among actual spikes. (b) Schematic of the process for SMS. A pyramid-like spike with a “frame structure” appears at step iii. (c) and (d) Cross-sectional and top-view SEM images, respectively, of SMS25.

region between 50 and 90 mV. The stable potential indicates the formation of a single Li-Si phase during the charging from 30 to $112 \mu\text{A h cm}^{-2}$. The charge consumption between 1.7 V and 0.5 V is mainly due to the irreversible reduction of the electrolyte, which leads to the SEI layer formation.¹ The Coulombic efficiency was therefore relatively low for the 1st cycle and increased during the following charge/discharge cycles, indicating stabilization of the electrode/electrolyte interface that allows reversible lithiation/delithiation of the electrode. Figure 2(b) shows dQ/dV profiles during the first 5 cycles, which clearly highlight the lithiation process evidenced by the charge consumption below 0.4 V. The appearance of multiple peaks in the dQ/dV profiles of both charge and discharge processes, whose intensity indicates the rate of lithiation of materials at each potential, is consistent with previous reports.^{1,6,9,11,25,26} Two peaks that appeared at 0.3 and 0.45 V during the discharge process from the 1st cycle are typical signals of delithiation from amorphous Li_xSi , suggesting that Li alloying of crystalline Si has already occurred in the lithiation process before, probably at potentials under 0.4 V.²⁴ From 2nd cycles, lithiation of amorphous Si started, as indicated by the peaks at 0.20–0.22 V and 0.25–0.28 V.

FIG. 2. (a) Charge/discharge curves and (b) dQ/dV profiles during first 5 cycles of galvanostatic cycling on a half-cell with SMS25.

The position and the amplitude of these peaks slightly evolved during the first few cycles and were then stabilized after the 3rd cycle, similarly to typical delithiation peaks at 0.30–0.35 V and 0.48–0.50 V.

Figure 3(a) shows the evolution of the discharge capacity per area, C_a , of the same half-cell as in Fig. 2, under the conditions of charge limits (Q_L) and current densities (J_a) changed during the cycling. For all Q_L attempted, from 112 to $448 \mu\text{A h cm}^{-2}$, the cycling was quite stable with a Coulombic efficiency higher than 99% except for the first few cycles due to the irreversible charge consumption during the SEI layer formation. However, the improvement of the Coulombic efficiency indicates that a stable SEI layer was formed relatively fast. Several dQ/dV profiles are depicted from the cycling with various Q_L and shown in Fig. 3(b), indicating that all the lithiation and delithiation peaks are enhanced as the charge limit Q_L increases. A slight shift of the lithiation peak at ~ 0.25 V to the lower potential as Q_L increases may indicate the increase of averaged x in Li_xSi . To confirm the reproducibility and the durability, we prepared another half-cell with SMS25 (chip area of 48 mm^2) and performed a longer cycling on it. During the whole period of the experiment until 342 cycles, where J_a varied between 200 and $500 \mu\text{A cm}^{-2}$ during the first 106 cycles then fixed at $400 \mu\text{A cm}^{-2}$ after 107th cycle, full charge/discharge occurred up to the charge limit without fading,

FIG. 3. (a) Evolution of discharge capacity and Coulombic efficiency on the same half-cell as shown in Fig. 2 during 136 cycles, with varying charge limit Q_L and current density J_a . (b) The dQ/dV profiles at 2nd, 38th, 74th, and 108th cycles. Q_L for each cycle was 112, 224, 336, and 448 μA h cm⁻², respectively. (c) Evolution of discharge capacity and Coulombic efficiency on another half-cell with SMS25 during 342 cycles.

indicating good stability of the SMS structure [Fig. 3(c)]. It is noteworthy that the charge/discharge cycles on a Si anode, not separated from the Si wafer, without any diffusion barrier layer, resulted in such excellent stability.

Besides, the divergence of negative dQ/dV occurred at the end of charge processes from the 1st cycle throughout the measured cycles [Figs. 2(b) and 3(b)]. This divergence at around 0.1 V of potential, which corresponds to the lithiation of crystalline Si,²⁴ is understood as a part of the bulk Si being lithiated in every charging step up to ≥108th cycles. However, the insertion of Li into the bulk Si was minimized,

thanks to the charge limit that was set considering the volume of the SMS layer; without this charge limit, i.e., if the charge process was limited only in potential, the lithiation would continue until the volume expansion would cause the destruction of the Si anode. One reason for better cyclability in the present results compared to previous ones on a black Si-based half-cell is obviously this limitation of charge. The present experiment, as well as previous studies, strongly suggests the significance of limiting the charge in charge/discharge cycling on Si anodes that are connected to the bulk Si wafer.^{9,18}

In the present paper, we describe the capacity and the current density per unit area, instead of those per unit mass, because of the difficulty in precisely estimating the mass of the Si material that actually takes part in lithiation. At the beginning, we roughly estimated from SEM images the areal density, M , of the SMS layer in SMS25 to be 1.7×10^{-4} g cm⁻². This M would convert the areal capacity C_a of 448 μA h cm⁻² to a gravimetric capacity C_m of 2665 mA h g⁻¹, and the areal current density J_a of 500 μA cm⁻² to a gravimetric current density J_m of 3.0 A g⁻¹ (or to a C-rate J_C of 0.7C, where 1C = 4.2 A g⁻¹). This combination of C_m and J_C values is, however, exceptional in comparison to previous reports on Si anodes. It is a general nature of the electrodes that a higher current density results in less specific capacity. One can find a universal relationship between gravimetric specific capacities and C-rates for various types of Si anodes previously reported, at least in a low J_C region up to ~2C, as plotted in Fig. 4.^{1,5,6,8,27} The point of 0.7C and 2665 mA h g⁻¹ (Point A in Fig. 4) seems to position out of this universal relationship. This anomaly should originate in the discrepancy between estimated and actual M values. We now try an approximation by drawing a line of $\log C_m - \log J_C = \text{constant}$, as shown in Fig. 4. Depending on M , the point (J_C , C_m) moves on this line, due to the relationships $C_m = C_a/M$ and $J_C = J_a/(C_m \cdot M)$. Although it is extremely difficult to obtain the true M value, it is certain that the true (J_C , C_m) point exists somewhere on this

FIG. 4. Relationship between gravimetric specific capacities (C_m) and C-rates (J_C) on various types of Si anodes (depicted from Refs. 1, 5, 6, 8, and 27). Points A and B show the present result assuming areal densities of the Si anode of 1.7×10^{-4} and 2.2×10^{-4} g cm⁻², respectively. Dashed line represents a line of constant ($\log C_m - \log J_C$) line that passes Point A.

FIG. 5. Nyquist diagrams of impedance measurements performed after (a) 1st, 6th, 36th cycles, and (b) 36th, 72nd, 106th, 136th cycles, on the same half-cell as shown in Fig. 2. Triangles indicate the points for a frequency of 435 Hz in each run.

line. It seems more realistic to assume that our point also obeys the universal relationship, positioning at Point B in Fig. 4, for example, which corresponds to an M of $2.2 \times 10^{-4} \text{ g cm}^{-2}$, i.e., the actual M of the active material was higher than that estimated from SEM images. If it is the case, it may imply that lithiation/delithiation occurred not only within the SMS layer but also in the bulk region. This picture is consistent with the divergence of discharge capacity at 0.1 V described above [Figs. 2(b) and 3(b)].

Figure 5 shows Nyquist diagrams based on electrochemical impedance measurements that were performed after certain charge/discharge cycles in Fig. 3(a). The semicircle with the characteristic frequency of several hundred Hz (435 Hz in this case) is generally attributed to the SEI layer, whereas the sloped line in the low frequency region represents the diffusion of Li ions into the bulk active material.^{4,28,29} The present cycling exhibited the drastic shrinkage of the semicircle during the first 36 cycles, followed by stabilization or a slight increase for further cycling, which behavior is consistent with previous reports on Si-based anodes.^{4,28} Ruffo *et al.* attributed the shrinkage of the semicircle at mid-frequency (250 Hz of characteristic frequency) during the first few cycles in their Si nanowire anode to the “fixation” of the SEI/liquid electrolyte interface.⁴ Then, the stabilization of the ac impedance signal and the diameter of the high-frequency semicircle can be explained by the stabilization of the interface, indicating that non-significant volume or surface changes are occurring on the electrode after the huge evolution observed during the first cycles. These observations are also supported by the SEM observation.

Figure 6 shows post-mortem SEM images of SMS25 electrodes after experiencing 136 and 342 charge/discharge cycles [corresponding to Figs. 3(a) and 3(c), respectively], together with the images of as-prepared SMS25 (namely, 0 cycle). The gap among pyramid-like spikes at the beginning [Fig. 6(b)] has been partially filled as the spikes deformed at the stage of 136th cycle [Fig. 6(d)], and has almost disappeared before the 342nd cycle [Fig. 6(f)]. We found neither crack on the surface nor detachment of the microstructured layer even after 342 cycles [Fig. 6(e)]. To understand what was occurring inside the SMS layer during cycling, an image at the edge of the SMS chip is informative. In a SEM image, at the edge of the SMS25 chip after 342 cycles [Fig. 7(a)], we can confirm that the microstructure layer still consists of a few μm -wide “fibers” even though the top surface shows the feature of a continuous plane.

FIG. 6. Oblique-view SEM images of SMS25 chips (a), (b) as prepared, (c), (d) after 136 charge/discharge cycles, and (e), (f) after 342 cycles. (a), (c), (e) are in a lower magnification and (b), (d), (f) are in a higher one.

FIG. 7. (a) Oblique-view SEM image of the edge of an SMS25 chip after 342 cycles. (b) Schematic of the model that the microstructure transforms from spiky into columnar during Li ion insertion.

As one side of the microstructure layer was open, the arrays of fibers near the edge were allowed to point tilted directions, clearly showing their fiber-like features. Note that the width of the fibers is almost constant from the bottom to the top, i.e., the microstructure has transformed from spiky into columnar. We also note that even the Si wafer base, as well as the columns, is free from any visible cracking. The quasi-smooth surface, the constant width of the fibers, and the lack of cracking all suggest the stabilization of the microstructure through the cycling, rather than the destruction of it.

On the basis of these experimental facts, we speculate a model on the deformation of SMS according to charge/discharge cycling, as illustrated in Fig. 7(b). When Li ions are inserted into a Si matrix of different thickness, the thicker (thinner) part would suffer from more (less) stress by the deformation. Especially, the thinnest parts with the thickness of less than 100 nm would be free from any destruction.¹⁴ Therefore, Li ions prefer entering the Si matrix at the thinner parts, where the volume expansion would cause less mechanical stress. In the case of a pyramid-like spike with graded widths, the top (bottom) part with a smaller (larger) width is supposed to absorb more (less) Li ions, until the width becomes uniform, i.e., the spike transforms into a column. It may also be possible to consider a picture that the top parts automatically absorb more Li ions because the electric field concentrates at the top with small radii or with the shortest distance to the counter electrode. The evaluation of possible

effects caused by these factors would bring about the strategies for designing anode forms and would require further studies. In the final form, the lithiation level from a microstructure to bulk regions would be graded along the depth, causing little risk of a point of discontinuous lithiation level, which could be the reason of destruction. This picture explains the fact that the present wafer-based Si anode did not show any cracks, in contrast to the previous ones.

The experiments on half-cells with SMS chips other than SMS25 (not shown) resulted in a tendency that the spikes with too short lengths are not durable for charge/discharge cycling. The discharge capacity of the cell with SMS40 (with the averaged height and width of 2.1 and 0.22 μm , respectively) has faded after 14 cycles, being accompanied by the cracking of the bulk Si layer. We summarize the results that the spikes of at least 5 μm -long, of pyramid-like outline with the graded width, with the thinnest part of less than 100 nm, as well as the limitation of charge, are important for the excellent cyclability of a wafer-based SMS Si anode. The “frame structure” [Fig. 1(b-iii)] is probably advantageous not only because of the thinness of the walls but also because of the mechanical robustness in comparison with other forms of material of same volume.

IV. CONCLUSIONS

We attempted to use SMS of Si (black-Si), prepared by a cryogenic DRIE process with an SF_6/O_2 gas mixture, for the anodes of Li half-cells. An SMS anode with spikes of 11 μm in averaged height revealed excellent stability without any destruction up to at least 340 charge/discharge cycles with a Coulombic efficiency higher than 99% under a limited capacity. The deformation of the microstructure from spiky to columnar implied the graded lithiation level along the length, which could result in the absence of a point with an abrupt change in mechanical stress. The present results suggest a possibility to prepare a LIB on a Si wafer, using cryoetched Si SMS as its anode. Thus, the way to integrate LIBs into industrial Si CMOS technology would be opened.
