Abstract The Pianosa Ridge forms the eastern flank of the Corsica Trough in the Northern Tyrrhenian Sea: it is the site of preferential accumulation of contourites and Mass Transport Deposits (MTDs). Along the Pianosa Ridge, eleven MTDs with a total volume of 6.5 km^3 were identified. These MTDs are distributed in three areas: A) one small MTD associated to canyon flank destabilisation in the northern part of the study area; B) six intermediate size MTDs in the central area; C) four MTDs of larger size (up to 2.62 km^3) to the south, including the Pianosa Slump, which is the most recent MTD in this area (aged at 42 to 50 kyr BP) and analysed in more detail. The main factor controlling the formation of MTDs in areas A and B seems to be steep slopes associated to erosion and heterogeneous sedimentation caused by bottom currents, respectively. In contrast, multiple factors may control slope instability in the zone where the largest MTDs took place (area C): the incision generated by contour currents, the presence of coarser layers in contourite drifts that may accumulate gas and the location of normal faults near the headwall.

Keywords Mass transport deposit, Contourite, Pockmark, Tyrrhenian Sea

1 Introduction

The Corsica Trough is located between Corsica and the Tuscan Shelf in the Northern Tyrrhenian Sea. It has a maximum depth of 900 m and connects the Tyrrhenian and Ligurian Seas. The eastern flank of the Corsica Trough is formed by the Pianosa Ridge, a tectonic structure with typical slopes between 3° and 10° , reaching 20° locally (Fig. 1). This area is characterised by several submarine landslides and contourite deposits (Cattaneo et al. 2014; Fig. 1). Contourite drifts are formed by the Levantine Intermediate Water (LIW), flowing northwards (Artale and Gasparini 1990) and generating stronger bottom currents on the Pianosa Ridge due to the Coriolis force. The sediment input from the Tuscan Shelf is low since sediment from Italian rivers is mostly trapped in the shelf and cannot reach the

Fig. 1 Seafloor gradient map of the Corsica Trough with superposed location of morpho-sedimentary features: Mass Transport Deposits (MTDs), contourite drifts and turbidite lobes (see legend). Three bathymetric cross-sections across areas A, B and C show the location of MTDs

Corsica Trough (Roveri 2002). Most of the sediment deposited in the Corsica Trough is transported from the Corsica shelf by the Golo turbidite network (Dep-tuck et al. 2008; Fig. 1).

The aims of this study are to present the size and the stratigraphic distribution of Mass Transport Deposits (MTDs) along the Pianosa Ridge, and to analyse their relationship with the pre-existing seabed morphology.

2 Material and Methods

In 2013 two cruises, PRISME2 and PRISME3 onboard the R/V *Atalante* and R/V *Pourquoi pas?*, respectively, took place along the Pianosa Ridge. Multibeam bathymetry, 72-channel high-resolution mini GI gun (50-250 Hz) and CHIRP (1800-5300 Hz) seismic reflection profiles, and Calypso piston cores were collected along the Pianosa Ridge. P-wave velocity was measured on whole core sections using a Geotek Multi-Sensor Core Logger (MSCL). The bulk sediment semi-quantitative geochemical composition was measured with an Avaatech X-ray fluorescence (XRF) core scanner on split cores. Radiocarbon dating was obtained from bulk planktonic foraminifera at the Poznan radiocarbon laboratory. Radiocarbon ages were corrected for a marine reservoir effect of 400 years and calibrated using Calib 7.0.2 radiocarbon calibration software and the IntCal13 calibration curve (Reimer et al. 2013). MTDs were identified by seismic facies validated by the analysis of equivalent coring samples. MTD volume was calculated using the Kingdom Suite ® software by quantifying the time interval between the top and the bottom of the MTD from the seismic profiles. The velocity applied for time-depth conversion (1550-1560 m/s) was obtained from the velocity analysis calculated with the ProMAX ® Seismic Processing Software.

3 Results

Along the Pianosa Ridge 11 MTDs were identified in the Quaternary sediment record. Differences in location, volume and morphology were used to distinguish three areas of MTDs: A, B and C (Table 1). Seismic correlation with the borehole GDEC4-2 (Fig.1; Angue Minto'o 2014) provided information about the stratigraphy in the region.

Area A shows a small submarine landslide associated to the destabilisation of the northern flank of the Elba Canyon (west of the Elba Island), where the slope is 8° to 20°. The headwall scarp and the deformation features of the MTD are clear in the bathymetry (Fig. 1). MTD A is of Holocene age, since it affects a regional reflector dated at 12 kyr.

Six small to intermediate size MTDs (B1 to B6) are observed in area B (Table 1). They are located west of the Pianosa Island, where the Pianosa Ridge forms an edge, generating in this zone high slope gradients (8-10°). The MTDs have an oval shape in plan view. B1, B2, B3 and B4 have a mean thickness of about 10 m; B5 and B6 mean thickness is 5 m. The continental slope in area B is starved during

Pliocene and Quaternary. Pre-Messinian deposits (age deduced by correlation with the well Martina 1; Figure 1; Pascucci et al. 1999) crop out in patches on the upper slope. Despite the reduced size of these MTDs, their thickness corresponds to about 30% of the Pliocene-Quaternary deposits in the lower continental slope. B6 and B5 MTDs are older than 542 kyr, while the sediment covering B4 was deposited at 452 kyr, based on correlation to the bottom of borehole GDEC4-2. B3 is close in time to B4 but separated by 300 kyr from B2 (Table 1). B1 is the most recent MTD (42-59 kyr) in area B, it took place about 80 kyr after B2. The frequency of MTDs in area B is irregular and it was higher during the Middle Pleistocene than during the Upper Pleistocene.

Four MTDs (C1 to C4) are located in area C, in the southern zone of the study area. Their volume ranges from 0.67 to 2.62 km³ and they are characterised by a high width/length ratio, except for C2 that has a ratio lower than 1 (Table 1). Between 265 and 380 kyr BP C3 and C4 were formed, followed by C2 at 125-160 kyr (Table 1). The Pianosa Slump (C1) is the most recent MTD of area C and it was analysed in more detail than the other MTDs since it was sampled by the Calypso piston core PSM3-CS022 (Figs. 2, 3). The top of C1 (i.e. the bottom of the post-slide hemipelagic sediment; Fig. 3) is dated at 42,326 cal yr BP and Cattaneo et al. (2014) report that the MTD disrupted sediments as old as 50,000 cal yr BP. C1 is overlain by about 17 to 20 m of sediment (Fig. 3). However, various morphological features related to MTD C1 can still be appreciated at the present seafloor (Fig. 2).

Table 1 Characterisation of Mass Transport Deposits in areas A, B and C

Area	Name	Volume (km ³)	Maximum runout (km)	Maximum length (km)	Width (km)	Width/Length ratio	Age (kyr BP)
A	A	0.10	1.5	1.2	3.6	3.0	<12
B	B1	0.19	7.0	5.7	7.6	1.3	42-59
	B2	0.09	8.0	5.6	4.6	0.8	125-137
	B3	0.26	7.5	5.9	7.2	1.2	420-437
	B4	0.15	4.2	2.5	7.4	3.0	452->542
	B5	0.05	6.0	3.4	4.4	1.3	>542
	B6	0.04	6.2	3.6	4.4	1.2	>542
C	C1	2.62	9.0	6.0	13.5	2.3	42-50
	C2	0.47	16.0	10.0	7.8	0.8	125-160
	C3	0.67	6.0	4.0	8.7	2.2	265-321
	C4	1.86	10.4	5.3	18.6	3.5	321-380

The headwall domain of C1 has the same lateral extent as the Pianosa Slump deposit. However, the headwall morphology is rather irregular. In the northern part, the headwall is continuous, parallel to a normal fault (Fig. 2b). It is connected to the MTD by a sidewall that is 30 m high at the present seafloor. South of this zone, the slope is cut by multiple discontinuous headwalls and scarps. C1 is composed of three main parts (Figs. 2b, 2c) deduced from seismic profiles, bathymetry and Calypso piston core PSM3-CS022 (Fig. 3): 1) strongly deformed sediment, 2) fold and thrust system and 3) tilted blocks. The strongly deformed sediment corre-

sponds to chaotic seismic facies that are present in the central northern part and in the southern part of C1, where the headwall is discontinuous. In this area the surface morphology shows lobate shapes and crests that indicate a movement towards the west that turned slightly to the southwest, in the direction of increasing depth. The MTD thickness of the southern part shows that there is a deposit at the foot of the slope up to 50 m thick and a thicker zone (50-70 m) in the central distal part.

Fig. 2 a Isopach map of the Pianosa Slump (C1) overlaying the present seafloor gradient map with the location of Calypso piston core PSM3-CS022 b Morphological interpretation of C1 c Multichannel high-resolution mini GI gun seismic reflection profile across MTDs C1, C3 and C4 and line drawing with the interpretation

In the northern part of C1 the internal structure of the deposit is more complex than in the southern part. In this area the toe domain of the MTD is formed by a fold and thrust system. The frontal part of C1 is composed of hemipelagites and turbidites that are deformed and compressed forming a system of thrusts, folds and pressure ridges, with individual pop-up blocks apparent in the frontal part of the MTD (Fig. 2). The greatest thickness of C1 deposits (up to 100 m) is found in the central zone of C1 where the pressure ridges are higher (up to 10 m high) and larger (up to 2 km long) (Fig. 2a). The proximal part consists of tilted blocks (Fig. 2b) that become more deformed towards the south. Tilted blocks are identified in seismic profiles where reflectors dip in different directions. Moreover, tilted blocks form crests that are apparent in the seafloor. Groundtruthing evidence of the presence of tilted blocks comes from the bottom of Calypso piston core PSM3-CS022 (Fig. 3). This core shows that a 4.7-m-thick debris flow deposit composed of mud with clay pebbles lies on top of the tilted blocks. These distinct seismic and lithological facies correspond to different degrees of deformation, which can be identified in the Calcium curve. When the degree of deformation is very high (debris flow deposit), the Calcium signal is very noisy (Fig. 3). Between the compressed frontal zone and the zone of tilted blocks, the sediment is strongly deformed, characterised by chaotic seismic facies and by a relatively smooth upper surface (Fig. 2). Since the pressure ridges and the crests are perpendicular to the mass movement, they provide information on the direction of the transport. The northern part of the Pianosa Slump comes from the area of the straight headwall parallel to the fault. The northernmost part moved slightly towards the northwest, while most of the sediment was transported in a southwest direction, towards the deepest part of the basin.

Multibeam bathymetry reveals the presence of many pockmarks located in the contourite drifts between areas B and C and close to MTDs in zone C (Fig. 1). The fluid escape paths over the Pianosa Slump are mainly found in the pressure ridges, in the crests and in the sidewall (Fig. 2b).

4 Discussion and Conclusions

Slope instability has been a recurrent process along the Pianosa Ridge, although the origin and the control factors could vary according to the location of the submarine landslides. The differences in size and volume between MTDs in area B and C are linked to an uneven sedimentation along the Pianosa Ridge related to the basement morphology and to bottom currents. Sediment accumulation on the slope in area C is much higher compared to area B. Therefore, more sediment could be potentially mobilised by mass transport during a single event, generating larger submarine landslides. In area B bottom currents are accelerated due to the higher slope gradient, preventing sediment deposition.

Group B and C present some similarities in the time intervals of slope failure, since B1-C1 and B2-C2 are in similar ranges of age. In contrast, the other MTDs

The red area shows a turbidite (peak in P-wave velocity), the orange area a debris flow deposit and the yellow area tilted blocks. Three calibrated radiocarbon ages are represented with red stars

are not synchronous. When C3 and C4 were formed, area B was in stable conditions (Table 1).

The main predisposing factor in areas A and B seems to be the steep slopes (8-20° and 8-10°, respectively) (Fig. 1). Within the Elba Canyon, due to the Coriolis effect, bottom currents could produce a stronger erosion on the northern flank of the canyon, generating the observed canyon asymmetry with a steeper northern flank (Fig. 1). Incisions and oversteepening on the northern flank might have contributed to the formation of MTD A. In area B, six MTDs are stacked, and represent a relevant percentage (30%) of the Pliocene-Quaternary deposit in the lower slope, suggesting that an important proportion of the sediment accumulated on the middle and upper slope was affected by mass transport. The formation of submarine landslides in area C (Fig. 1) seems to be much more complex. Multiple factors may predispose slope instability in this area. Bottom currents may have an important role since they provide sediment and generate incisions with higher slopes, corridors of non deposition or slight erosion (moat with slope of 15°; Fig. 1). In addition, layers of coarser sediment in contourite drifts seem to influence the

location of failure planes (Miramontes et al. 2014) and could potentially stock more gas than the overlying mud. Numerous pockmarks affect the present day seafloor on top of the MTDs and contourite drifts (Figs. 1, 2). Some of these pockmarks are clearly rooted on buried MTDs and turbidite lobes (Fig. 1). Such a configuration suggests that the emplacement of these sedimentary bodies might have influenced subsequent instability.

In the Pianosa Ridge the present-day seismicity is considered to be very low (Scisciani and Calamita 2009), while the area entered in a post-rift phase from the late Messinian (Pascucci et al. 1999). However, the location of the headwall of the Pianosa Slump next to a normal fault that affects the Pliocene-Quaternary record (Fig. 3) raises questions about the possible relationship between faulting and slope instability.

Acknowledgments We thank the Captain and the crew of the PRISME2 and PRISME3 cruises (2013) onboard R/V Atalante and R/V Pourquoi pas?, respectively. We are grateful to reviewers M. Rovere and C. Campbell for their valuable suggestions that improved the manuscript. The thesis of Elda Miramontes is co-funded by TOTAL and Ifremer as part of the scientific project TOTAL-Ifremer PAMELA. We thank projects LabexMER ANR-10-LABX-19-01 Axis 4 for lab support.
