This paper aims at establishing a simple yet efficient solution to the problem of trajectory tracking with input constraint of a nonlinear longitudinal vehicle model. We make use of differential flatness, by embedding the constraint into the reference trajectory design.

Keywords: flatness based control, automotive control, input constraints

1. Introduction

The aim of this paper is to come up with simple yet efficient control techniques for vehicle longitudinal speed control with constraint on its torque. More precisely, we consider a longitudinal nonlinear model including a simple adherence/friction law (see, e.g. (Ellis, 1969; Gillespie, 1992; Kiencke and Nielsen, 2000; Mitschke, Manfred ; Wallentowitz, 2004; Rajamani, 2011)). For this model, we consider the problem of tracking a reference speed trajectory with constraint on the input torque. Traditional treatment of such a problem include model predictive control (Li et al., 2011) and use of optimisation techniques (Hsu and Chen, 2013; Hsu et al., 2010) Some other works use adaptive anti-windup techniques (Kahveci and Ioannou, 2010; Tarbouriech and Turner, 2009), saturated inputs (Valmorbida et al., 2013) to name a few.

The constraint is embedded in the flat output trajectory design. Thus, the closed loop tracking controller naturally satisfies the required constraint, without the recourse to costly optimisation procedure. A key advantage of the advocated technique is that the physical meaning is kept throughout the whole process, a feature often lost in MPC or other optimisation based techniques.

More precisely, a dynamical system with m inputs is differentially flat (Fliess et al., 1995) if there exists a so-called flat output \( \omega \) with m components \( \omega = (\omega_1, \ldots, \omega_m) \) such that: first, these components are functions of the system's variables (endogenous character); second, the \( \omega \)'s are differentially independent, i.e. they don't satisfy a differential equation involving themselves only (independent character); third, all the system's variables can be expressed as nonlinear functions of the \( \omega \)'s and of a finite number of their derivatives (parametrisation property).

Thus, when a system variable is subject to a constraint, the latter is directly translated into a flat output constraint, thanks to the parametrisation property. The tracking problem with constraints is thus elaborated in two steps: first design a flat output reference trajectory \( \omega_r \) satisfying all the required constraints; second, design a closed loop feedback control law ensuring the tracking of \( \omega_r \) with stability. The constraints satisfaction is ensured by design, since it is embedded in the reference trajectory

*Corresponding author.
elaboration process.

The involved constraints can be given on any system variable, since all the system is parametrised by the flat output. The constraint is enforced on the reference variables, and is ensured practically on the actual variables since the tracking error is meant to tend to zero, in general exponentially.

Ensuring the constraints on the flat output is simplified by specialising the flat output reference trajectory to specific classes of functions with convenient properties, such as closedness wrt differentiation or being solution of a differential equation.

To the best of the author's knowledge, almost all the current work on differentially flat systems with constraints is managed through optimisation procedures (Chamseddine et al., 2013; Faiz et al., 2001; Flores and Milam, 2006; Keck et al., 2015; Petit and Sciarretta, 2011; Ross and Fahroo, 2004; Tsuei and Milam, 2016; Walambe et al., 2016). In (Löwis and Rudolph, 2003), no optimisation technique is used, but the flat output trajectory is not known on advance; thus, the trajectory is built step by step, by concatenating pieces. The only work partially related to our approach is (Ruppel et al., 2011), where the constraints appear solely on derivatives of the flat output, which is specialised to piecewise polynomial functions. Preliminary results related to the present one have been presented for linear systems with delays in (Bekcheva et al., 2017), and for an Euler Bernoulli beam in (Bekcheva et al., 2015). Other works related to the present theme include differential flatness based techniques for longitudinal and lateral vehicle dynamics (Menhour et al., 2014).

The paper is organised as follows. In the next Section, the model is recalled. In Section 3, the flatness of the model is established, and a closed loop feedback tracking controller is given in Section 4. The torque constraint management is dealt with in Section 5.

2. Longitudinal model

The equations of the vehicle dynamics can be written as follows (see, e.g. (Ellis, 1969; Gillespie, 1992; Kiencke and Nielsen, 2000; Mitschke, Manfred; Wallentowitz, 2004; Rajamani, 2011)) :

\[ m \ddot{V}_x = F_x \quad (2.1a) \]
\[ I_w \dot{\omega} = RT - rF_x - F_o \quad (2.1b) \]

with the following slip ratio and forces :

\[ F_x = \mu_s(\lambda)F_z, \quad \lambda = \frac{V_x - r\omega}{\max(V_x, r\omega)} \quad (2.2a) \]
\[ F_z = mg \quad (2.2b) \]
\[ F_o = -F_a - F_s \quad (2.2c) \]
\[ R_x = mgC_r, \quad F_a = \frac{\rho C_a V_x^2}{2}, \quad F_s = mg \sin \alpha \quad (2.2d) \]

The notations for the model (2.1a)–(2.1b) are: \( V_x \) is the longitudinal speed of the vehicle, \( m \) its mass, \( F_x \) the longitudinal tire force, \( I_w \) inertia moment of the wheel, \( \omega \) angular wheel speed, \( R \) the damping coefficient of the drive-line, \( T \) the engine torque, \( r \) the effective tire radius, \( F_o \) the other forces exerted on the car body.

The expressions of the forces are given in Equations (2.2a)–(2.2d), with the following notations: \( \mu_s \) is the adherence function, \( F_z \) the normal force on the tire, \( \lambda \) the slip ratio, \( g \) the gravity constant, \( R_x \) the rolling resistance force, \( F_a \) the longitudinal aerodynamic drag force, \( \rho \) is the air volumic mass, \( A \) is
frontal area of the vehicle, $C_a$ is the drag coefficient, $F_s$ the force due to the road slope, and $\alpha$ the road slope angle.

A possible model for $\mu(\lambda)$ introduced by Kiencke and Däß and depicted in Figure 1, is given by the function:

$$
\mu_{x}(\lambda) = \frac{a\lambda}{b + c|\lambda| + \lambda^2}
$$

One easily obtains that the maximum $\mu^*$ of such a curve occurs at $\lambda^*$ with:

$$
\lambda^* = \sqrt{\frac{\mu^*}{\mu_1}}, \quad \mu^* = \frac{a}{c + 2\sqrt{b}}
$$

Conversely, the constants $a, b, c$ can be expressed as functions of $\mu^*, \lambda^*$ and $\mu_1$:

$$
a = \frac{\mu^*(1 - \lambda^*)^2}{\mu^* - \mu_1}, \quad b = \lambda^*^2, \quad c = \frac{\mu_1(1 + \lambda^*^2) - 2\mu^*\lambda^*}{\mu^* - \mu_1}
$$

where $\mu_1 = \mu(1)$ is the value of the function $\mu$ at $\lambda = 1$ (i.e. at wheel lock). Note that $a$ and $b$ are strictly positive constants.

**Remark 2.1** Another, quite popular, model is the Pacejka one (Bakker et al., 1987; Pacejka, 2006). We have not used the latter, for simplicity reasons, but a similar, although more complex, analysis could be made with Pacejka’s model.

The measured outputs are traditionally the wheel speed (e.g. through ABS encoders). We shall here suppose that the speed $V_x$ of the vehicle’s center of gravity is either measured or reconstructed via an observer or an estimator (see, e.g. a previous work of some author of the present paper (Villagra et al., 2008)).

### 3. Differential flatness of the model

The model (2.1) is trivially flat, with flat output $V_x$. Indeed,

$$
\dot{V}_x = g \mu_x(\lambda)
$$

![Adherence function $\mu(\lambda)$.](image-url)
Then,

$$\lambda = \mu^{-1} \left( \frac{V_x}{g} \right)$$  \hspace{1cm} (3.2)

Now one has to distinguish two acceleration and deceleration cases (implied by the form of $\lambda$ in (2.2a)):

- Acceleration case, where $r\omega \geq V_x$

  $$\lambda = \frac{V_x}{r\omega} - 1 = \mu^{-1} \left( \frac{V_x}{g} \right)$$

  Hence

  $$\omega = \frac{V_x}{r \left[ 1 + \mu^{-1} \left( \frac{V_x}{g} \right) \right]}$$  \hspace{1cm} (3.3)

  And thus

  $$\ddot{V}_x = g\mu_x' (\lambda) \dot{\lambda} = g\mu_x' (\lambda) \frac{1}{r\omega^2} (\omega V_x - \dot{\omega} V_x)$$

- Deceleration case, where $r\omega \leq V_x$

  $$\lambda = 1 - \frac{V_x}{r\omega} = \mu^{-1} \left( \frac{V_x}{g} \right)$$

  Hence

  $$\omega = \frac{V_x}{r \left[ 1 - \mu^{-1} \left( \frac{V_x}{g} \right) \right]}$$  \hspace{1cm} (3.4)

  And thus

  $$\ddot{V}_x = g\mu_x' (\lambda) \dot{\lambda} = g\mu_x' (\lambda) \frac{r}{V_x^2} (\omega V_x - \dot{\omega} V_x)$$

Thus, one has the following dynamics in $V_x$:

$$\ddot{V}_x = \frac{g\mu_x'}{\max \left( r\omega^2, \frac{V_x^2}{r} \right)} \left[ \omega V_x + \frac{V_x}{I_w} \left( mrV_x + F_o + RT \right) \right]$$  \hspace{1cm} (3.5)

and the control input $T$ is then obtained as

$$T = \frac{1}{R} \left[ \left( mr + \frac{I_w \omega}{V_x} \right) \dot{V}_x + F_o - \frac{I_w \max \left( r^2 \omega^2, \frac{V_x^2}{r} \right)}{g RV_x \mu_x'} \dot{V}_x \right]$$  \hspace{1cm} (3.6)
The reader could have the (quite normal) feeling that the laws (3.3) and (3.4) yield a discontinuity when the vehicle switches from acceleration to deceleration (leading to a chattering like phenomenon). First note that this can only occur at extremely low slip, i.e. when \( r\omega - V_x \ll 1 \), where the \( \mu() \) curve is in the linear zone (and thus the \( \mu^{-1} \) also); thus

\[
\mu^{-1}\left(\frac{\dot{V}_x}{g}\right) \approx \beta \frac{\dot{V}_x}{g}
\]

Moreover, when the vehicle switches from acceleration to deceleration (or vice-versa), one has \(|\dot{V}_x| \ll 1\). Thus, in (3.3), one has

\[
\frac{1}{1 + \mu^{-1}\left(\frac{V_x}{g}\right)} = 1 - \mu^{-1}\left(\frac{\dot{V}_x}{g}\right) + o\left(\left(\frac{\dot{V}_x}{g}\right)^2\right)
\]

Thus, the expression of \( \omega \) is

\[
\omega = \frac{V_x}{r}\left[1 - \mu^{-1}\left(\frac{\dot{V}_x}{g}\right) + o\left(\left(\frac{\dot{V}_x}{g}\right)^2\right)\right]
\]

whose term in \( o((V_x/g)^2) \) is exactly the one of (3.4). Thus, in case of acceleration-deceleration switching, the expression of \( \omega \) is continuous and differentiable.

4. Trajectory tracking

4.1 Trajectory tracking control law

Recalling the flat output dynamics (3.5), and setting the right member equal to a new input \( v \), one obtains the linearizing feedback

\[
\omega \ddot{V}_x + \frac{V_x}{T_w} (mr \dot{V}_x + F_o + RT) = \max\left(r^2 \omega^2, \frac{V_x^2}{\mu'_x}\right) v
\]

tranforming the flat output dynamics (3.5) to

\[
\ddot{V}_x = v
\]

Setting the new input \( v \) to

\[
v = \ddot{V}_{sr} - K_p e_{V_x} - K_d \dot{e}_{V_x}, \quad e_{V_x} = V_x - V_{sr}
\]

with \( K_p, K_d > 0 \) yield an exponentially stable error dynamics. The original input is then obtained as

\[
T = \frac{1}{R} \left[\left(\frac{mr}{V_x} \omega + \frac{I_w}{V_x} \right) \dot{V}_x + F_o - \frac{I_u \max\left(r^2 \omega^2, \frac{V_x^2}{\mu'_x}\right)}{g r V_x \mu'_x} v\right]
\]

\[
v = \ddot{V}_{sr} - K_p e_{V_x} - K_d \dot{e}_{V_x}
\]

Remark 4.1 Note that, in (4.2), one could have used equally a second order sliding mode or a model free control law, for instance, in order to gain in robustness.
4.1.1  Open and closed loop tracking. Let \( V_{xr} \) a reference trajectory for the flat output \( V_x \). Denoting by \( T_r \) the following open loop control law, one has by direct substitution from (3.6):

\[
T_r = \frac{1}{R} \left[ \left( m_r \omega_r \right) V_{xr} + F_o - \frac{I_r \omega_r^2 V^2_{xr}}{grV_x \mu'_x} \right] \tag{4.3}
\]

Thus, the Equations (4.1)–(4.2) can be rewritten as

\[
T = T_r - \frac{1}{R} \left( K_p e + K_d \dot{e} V_x \right) \tag{4.4}
\]

We thus see that, if the error \( e \) and its derivative \( \dot{e} \) remain small (which is the case when the tacking performance is good), the closed loop torque \( T \) remains close to the open loop one \( T_r \).

4.2  Trajectory tracking scenario

4.2.1  Trajectory form. We shall choose a trajectory \( V_{xr}(t) \) of the following form

\[
V_{xr}(t) = \Omega_{p_u,p_d}(t) = \Theta_{p_u}(t) - \Theta_{p_d}(t) \tag{4.5}
\]

\[
\Theta_{p_u}(t) = \frac{V_{hs} - V_{ls}}{2(t_{es} - t_{bs})} \left( \log Ch_{\sigma_x}(t - t_{bs}) + \log Ch_{-\sigma_x}(t - t_{es}) \right) + \frac{V_{hs} - V_{ls}}{2} \tag{4.6}
\]

\[
\log Ch_{\sigma}(t) = \frac{1}{\sigma} \log \left( \cosh (\sigma t) \right)
\]

\[
P_u \in \left\{ p_u, p_d \right\}, \quad p_u = (t_{bs}, t_{eu}, V_{lu}, V_{hu}, \sigma_u), \quad p_d = (t_{bd}, t_{ed}, V_{ld}, V_{hd}, \sigma_d)
\]

The forms of \( \Omega_{p_u,p_d} \) and \( \Theta_p \) are depicted in Figures 2 and 3. The speeds \( V_{ls} \) and \( V_{hs} \) are the beginning and reached speeds, respectively; \( t_{bs} \) and \( t_{es} \) are the beginning and ending times of speed change. The real \( \sigma_x \) is a stiffness parameter: the higher \( \sigma_x \), the closer \( \log Ch_{\sigma_x}(t) \) is from \( |t| \).

**Remark 4.2** One could have chosen a tanh-like trajectory for \( V_{xr} \). The chosen form (which amounts to a combination of primitives of tanh) is a smooth (in fact entire) approximation of a trajectory yielding a piecewise constant acceleration. The difference \( t_{es} - t_{bs} \) is related to the acceleration, while the stiffness \( \sigma \) is related to the jerk. A tanh-like trajectory would furnish only a single design parameter (the stiffness).

The associated trajectory parameters are: \( \sigma = 0.5, t_{bu} = 20s, t_{eu} = 35s, t_{bd} = 70s, t_{ed} = 85s \).

4.2.2  A physical constraint. Using Eq. (2.1a), p. 2, we have

\[
\dot{V}_x = g \mu_s(\lambda)
\]

Since the \( \mu_s \) curve is imposed by the tyre/ground physics, we should ensure that \( \dot{V}_x \) does not exceed the maximum (resp. minimum) of \( g \mu_s \). In other words, the chosen trajectory will be such that the physical constraint

\[
|\dot{V}_{xr}| \leq g \max_{\lambda \in [-1,1]} (\mu_s(\lambda)) \tag{4.7}
\]
is met, where

$$\max_{\lambda \in [-1,1]} (\mu(\lambda)) = \mu_*(\lambda^*) = \mu^*$$

is given by (see Eq. (2.3) and below)

$$\mu^* = \frac{a}{c + 2\sqrt{b}}, \quad \text{with} \quad \lambda^* = \sqrt{b}$$

We shall consider the following

$$\max_{t \in \mathbb{R}} |\dot{V}_{x_r}(t)| = g(\mu^* - \epsilon \mu) \triangleq g\mu_M$$

(4.8)

where \(\epsilon\mu\) is such that \(\epsilon\mu / \mu^* \ll 1\). This corresponds to

$$\lambda_M = \mu^{-1}(\mu_M) = \lambda^* - \epsilon \lambda$$

(4.9)

where \(\epsilon\lambda\) is such that \(\epsilon\lambda / \lambda^* \ll 1\).

### 4.2.3 Trajectory tracking

The trajectory tracking of \(V_{x_r} = \Omega_{p_u, p_d}(t)\) is depicted in Figures 4 and 5. The chosen parameters are the following: initial conditions \(V_{x0} = 5\) m/s, \(\omega_0 = 16.67\) rad/s, starting speed \(V_{lu} = V_{ld} = 5\) m/s, reached speed \(V_{hu} = V_{hd} = 15\) m/s. We see on Fig. 4 and 5 that the trajectory tracking is achieved with a very good precision, since the maximum error \(V_{x} - V_{x_r}\) in Fig. 5 is \(2.055.10^{-5}\). The slip ratio \(\lambda\) and the adherence function \(\mu(\lambda)\) are plotted in Figures 6 and 7. Remark that this slip ratio \(\lambda\) remains very small (the maximum of \(\lambda\) is \(4.613.10^{-4}\)). The parameters of the function \(\mu(\lambda)\) are: \(a = 3.661, b = 0.022, c = 5.153\).
The control law $T$ and the error $T - T_r$ are depicted in Figures 8 and 9. The chosen feedback gains are: $K_p = 200$, $K_d = 10$. Finally, the closed loop torque $T$ is very close to the open loop torque $T_r$, as can be seen on Fig. 9: the maximum error (in absolute value) $T - T_r$ is $-1.4 \times 10^{-6}$. 
5. Torque constraint management

Since the constraints will be expressed in terms of the flat output $V_x$ and its derivatives, we have to compute analytically the first derivatives of $V_x$.

5.1 Trajectory first derivatives

The derivatives of $\Omega$ are the following:

\[
\dot{V}_{xr} = \dot{\Omega}_{p_p, p_d}(t) = \frac{V_{hu} - V_{lu}}{2(t_{eu} - t_{bu})} (\tanh (\sigma_u(t - t_{bu})) + \tanh (\sigma_u(t - t_{eu})) - \frac{V_{hd} - V_{ld}}{2(t_{ed} - t_{bd})} (\tanh (\sigma_d(t - t_{bd})) + \tanh (\sigma_d(t - t_{ed})))
\]

\[
\ddot{V}_{xr} = \ddot{\Omega}_{p_p, p_d}(t) = \frac{\sigma_u(V_{hu} - V_{lu})}{2(t_{eu} - t_{bu})} (\tanh^2 (-\sigma_u(t - t_{eu})) - \tanh^2 (\sigma_u(t - t_{bu}))) - \frac{\sigma_d(V_{hd} - V_{ld})}{2(t_{ed} - t_{bd})} (\tanh^2 (\sigma_d(t - t_{ed})) - \tanh^2 (\sigma_d(t - t_{bd})))
\]

For the example depicted in Figure 2, we get the derivatives in Figures 10 and 11. The maximum and minimum of $\dot{\Omega}_{p_p, p_d}$ and $\ddot{\Omega}_{p_p, p_d}$ are

\[
\max(\dot{\Omega}_{p_p, p_d}(t)) = \frac{V_{hu} - V_{lu}}{2(t_{eu} - t_{bu})}, \quad \min(\dot{\Omega}_{p_p, p_d}(t)) = -\frac{V_{hd} - V_{ld}}{2(t_{ed} - t_{bd})}
\]

\[
\max(\ddot{\Omega}_{p_p, p_d}(t)) = \frac{\sigma_u(V_{hu} - V_{lu})}{2(t_{eu} - t_{bu})} - \frac{\sigma_d(V_{hd} - V_{ld})}{2(t_{ed} - t_{bd})}
\]

\[
\min(\ddot{\Omega}_{p_p, p_d}(t)) = -\max(\dot{\Omega}_{p_p, p_d}(t))
\]
Torque expression and simple bounds

We shall give in this Subsection various bounds, postponing a discussion about them to Subsection 5.3, p. 12.

5.2 Torque expression amenable to be bounded

Recall the expression obtained for the trajectory tracking feedback law in Eq. (4.1):

\[ T = \frac{1}{R} \left[ \left( mr + \frac{J_\omega}{V_x} \right) \ddot{V}_x + F_o - \frac{I_m \max(r^2 \omega^2, V_x^2)}{grV_x \mu_s} \dot{V}_x \right] \]

Then, we have:

- In the acceleration case, where \( r \omega \geq V_x, \lambda \leq 0 \)

\[ \frac{\omega}{V_x} = \frac{1}{r(1 + \lambda)} \]

- In the deceleration case, where \( r \omega \leq V_x, \lambda \geq 0 \)

\[ \frac{\omega}{V_x} = \frac{1 - \lambda}{r} \]

Thus, the expression for the torque is
• In the acceleration case
\[ T = \frac{1}{R} \left[ \left( mr + \frac{I_w}{r(1+\lambda)} \right) \dot{V_x} + F_o + \frac{I_w}{gr\mu'_x(1+\lambda)^2} V_x \ddot{V}_x \right] \]

• In the deceleration case
\[ T = \frac{1}{R} \left[ \left( mr + \frac{I_w(1-\lambda)}{r} \right) \dot{V_x} + F_o - \frac{I_w}{gr\mu'_x} V_x \ddot{V}_x \right] \]

5.2.2 Generic bound. We have the following bounds for $|T|$:  

• In the acceleration case
\[ |T| \leq \frac{1}{R} \left[ \left( mr + \frac{I_w}{r(1+\lambda)} \right) \dot{V_x} + |F_o| + \frac{I_w}{gr\mu'_x(1+\lambda)^2} V_x |\ddot{V}_x| \right] \quad (5.6) \]

• In the deceleration case
\[ |T| \leq \frac{1}{R} \left[ \left( mr + \frac{I_w(1-\lambda)}{r} \right) |\dot{V_x}| + |F_o| + \frac{I_w}{gr\mu'_x} V_x |\ddot{V}_x| \right] \quad (5.7) \]

5.2.3 A simplistic bound. A simplistic bound is given by considering minimum (in denominators) and maximum (in numerators) values for the various expressions in the bounding formulas (5.6)–(5.7):

• In the acceleration case
\[ |T| \leq \frac{1}{R} \left[ \left( mr + \frac{I_w(1+\lambda)}{r} \right) \dot{V}_{\delta M} + \frac{I_w}{gr\mu'_{\delta M}(1+\lambda)^2} V_{\delta M} |\ddot{V}_{\delta M}| \right] \quad (5.8) \]

• In the deceleration case
\[ |T| \leq \frac{1}{R} \left[ \left( mr + \frac{I_w(1-\lambda)}{r} \right) |\dot{V}_{\delta M}| + \frac{I_w}{gr\mu'_{\delta M}} V_{\delta M} |\ddot{V}_{\delta M}| \right] \quad (5.9) \]

with the following notations (see, in particular, Eq. (4.9))
\[ \dot{V}_{\delta M} = \max \left( \frac{\Delta V_u}{\Delta \mu}, \frac{\Delta V_d}{\Delta \mu} \right), \quad \ddot{V}_{\delta M} = \max \left( \frac{\sigma_u \Delta V_u}{\Delta \mu}, \frac{\sigma_d \Delta V_d}{\Delta \mu} \right) \quad (5.10) \]
\[ \lambda_m = -\lambda_M = \mu^{-1}(\mu_M) = -\lambda^* + \epsilon \lambda, \quad \mu_m' = \mu'(\lambda^* - \epsilon \mu') \quad (5.11) \]

5.2.4 A simple but realistic bound. We shall then consider the following more realistic bounding function:

• In the acceleration case
\[ |T| \leq \left( \frac{mr}{R} + \frac{I_w}{rR(1+\lambda_m)} \right) \dot{V}_x + \max \left( \frac{I_w V_x|\ddot{V}_x|}{grR\mu'_x(1+\lambda_r)^2} \right) = \xi_{\delta M} \dot{V}_x + \zeta_{\delta M} \quad (5.12) \]

• In the deceleration case
\[ |T| \leq \left( \frac{mr}{R} + \frac{I_w(1-\lambda_m)}{rR} \right) |\dot{V}_x| + \max \left( \frac{I_w V_x|\ddot{V}_x|}{grR\mu'_x} \right) = \xi_{\delta M} V_x + \zeta_{\delta M} \quad (5.13) \]
5.3 Discussion and bounds fulfilment

5.3.1 Generic bound. The bound given in Equations (5.6)–(5.7) is rather generic, since it contains expressions in $\lambda$, yielding expressions in $V_x$ (see, e.g. Eq. (3.2)). Thus, it cannot be used very simply.

5.3.2 Simplistic bound. The simplistic bound of Equations (5.8)–(5.9) are far too pessimistic. Indeed, e.g. for the trajectory given in Figure 4, p. 8, the above bound in the acceleration case is $9696.828\text{N}$, when the real maximum on $T$ is $1.948\text{N}$. It is thus unusable.

5.3.3 A simple but realistic bound. The simple bound given in Equations (5.12)–(5.13) yields a maximum of $1.962\text{N}$, which is a much better bound than the previous one, wrt the real maximum of $1.948\text{N}$.

REMARK 5.1 Note that the bounding functions (5.12)-(5.13) are valid for any type of reference trajectory, and not only the one given in (4.5), p. 6.

Recall the form of the bounds given in (5.3)

$$\dot{V}_{sm} = -\frac{\Delta V_d}{\Delta t_d}, \quad \dot{V}_{sM} = \frac{\Delta V_u}{\Delta t_u}$$

$$\Delta V_u = V_{hu} - V_{lu}, \quad \Delta V_d = V_{hd} - V_{ld}, \quad \Delta t_u = t_{eu} - t_{bu}, \quad \Delta t_d = t_{ed} - t_{bd}$$

and suppose $\Delta V_u$ and $\Delta V_d$ being given by practical considerations (e.g. speed limits). From the bounds obtained in (5.12)–(5.13), we then have

- In the acceleration case

$$|T| \leq \xi_{aM} \dot{V}_{x} + \zeta_{aM} \leq \xi_{aM} \dot{V}_{sM} + \zeta_{aM} = \xi_{aM} \frac{\Delta V_u}{\Delta t_u} + \zeta_{aM} \quad (5.14)$$

- In the deceleration case

$$|T| \leq \xi_{dM} \dot{V}_{x} + \zeta_{dM} \leq -\xi_{dM} \dot{V}_{sm} + \zeta_{dM} = \xi_{dM} \frac{\Delta V_d}{\Delta t_d} + \zeta_{dM} \quad (5.15)$$

Then, to ensure some prescribed bound on the the torque

$$|T| \leq T_{Ma} \text{ on acceleration, and } |T| \leq T_{Md} \text{ on deceleration} \quad (5.16)$$

it is sufficient to impose the following bounds on $\Delta t_u$, $\Delta t_d$:

$$\Delta t_u > \frac{\xi_{dM} \Delta V_d}{T_{Md} - \zeta_{dM}}, \quad \Delta t_d > \frac{\xi_{aM} \Delta V_u}{T_{Ma} - \zeta_{aM}}$$

In Figure 12, we have the bounds (5.12)–(5.13) in dashed line (\( \xi_{aM} \dot{V}_{x} + \zeta_{aM} \) and \( \xi_{dM} \dot{V}_{x} + \zeta_{dM} \)) and the torque $T$ in solid line, and in Figure 13 is depicted the error between the previous two. Note that the maximum error is $1.398\times10^{-2}$, which is $0.18\%$ of $T_r$’s maximum.
6. Conclusion

We have elaborated a simple yet efficient scheme for tracking a reference speed of a longitudinal vehicle model with torque constraint. The flatness character of the model enabled to embed the constraint fulfilment in the trajectory design. We considered a special class of functions for the class output, namely combinations of \( \log(\cosh(t)) \) type functions.

More general classes of functions will be considered in the future, together with some other types of constraints.
