ABSTRACT

In this paper, we address a relatively new task: prediction of ASR performance on unseen broadcast programs. We first propose an heterogenous French corpus dedicated to this task. Two prediction approaches are compared: a state-of-the-art performance prediction based on regression (engineered features) and a new strategy based on convolutional neural networks (learnt features). We particularly focus on the combination of both textual (ASR transcription) and signal inputs. While the joint use of textual and signal features did not work for the regression baseline, the combination of inputs for CNNs leads to the best WER prediction performance. We also show that our CNN prediction remarkably predicts the WER distribution on a collection of speech recordings.

Index Terms— Performance Prediction, Large Vocabulary Continuous Speech Recognition, Convolutional Neural Networks.

1. INTRODUCTION

Predicting automatic speech recognition (ASR) performance on unseen speech recordings is an important Grail of speech research. From a research point of view, such a task helps understanding automatic (but also human) transcription performance variation and its conditioning factors. From a technical point of view, predicting the ASR difficulty is useful in applicative workflows where transcription systems have to be quickly built (or adapted) to new document types (predicting learning curves, estimating the amount of adaptation data needed to reach an acceptable performance, etc.).

ASR performance prediction from unseen documents differs from confidence estimation (CE). While CE systems allow detecting correct parts as well as errors in an ASR output, they are generally trained for a particular system and for known document types. On the other hand, performance prediction focuses on unseen document types and the diagnostic may be provided at broader granularity, at document level for instance\textsuperscript{1}.

Moreover, in performance prediction, we may not have access to the ASR system investigated (no lattices nor N-best hypotheses, no internals of the ASR decoding) which will be considered as a black-box in this study.

\textsuperscript{1}Nevertheless this paper will analyze performance prediction at different granularities, from fine to broad grain: utterance, collection.

Contribution This paper proposes to investigate a new task: prediction of ASR performance on unseen broadcast programs. Our first contribution is methodological: we gather a large and heterogenous French corpus (containing non spontaneous and spontaneous speech) dedicated to this task and propose an evaluation protocol. Our second contribution is an objective comparison between a state-of-the-art performance prediction based on regression (engineered features) and a new strategy based on convolutional neural networks (learnt features). Several approaches to encode the speech signal are investigated and it is shown that both (textual) transcription and signal encoded in a CNN lead to the best performance.

Outline The paper is organized as follows. Section 2 is a brief overview of related works. Section 3 details our evaluation protocol (methodology, dataset, metrics). Section 4 presents our ASR performance prediction methods and 5 the experimental results. Finally section 6 concludes this work.

2. RELATED WORKS

Several works tried to propose effective confidence measures to detect errors in ASR outputs. Confidence measures were introduced for OOV detection by\textsuperscript{11} and extended by\textsuperscript{12} who used word posterior probability (WPP) as confidence measure for ASR. While most approaches for confidence measure estimation use side-information extracted from the recognizer\textsuperscript{13}, methods that do not depend on the knowledge of the ASR system internals were also introduced\textsuperscript{14}.

As far as the WER prediction is concerned,\textsuperscript{5} proposed an open-source tool named TranscRater based on feature extraction (lexical, syntactic, signal and language model features) and regression. Evaluation was performed on CHiMe-3 data and interestingly it was shown that signal features did not help the WER prediction.

One contribution of our paper is to encode signal information in a CNN for WER prediction. Encoding signal in a CNN has been done in several speech processing front-ends\textsuperscript{6,7,8}. Some recent works directly used the raw signal for speech recognition\textsuperscript{7,9} or for sound classification\textsuperscript{10}.

3. EVALUATION FRAMEWORK

We focus on ASR performance prediction on unseen speech data. Our hypothesis is that performance prediction systems
should only use the ASR transcripts (and the signal) as input in order to predict the corresponding transcription quality. Obviously, reference (human) transcriptions are only available during training of the prediction system. A Trainpred corpus contains many pairs {ASR output, Performance} (more than 75k ASR turns in this work), a Testpred corpus only contains ASR outputs (more than 6.8k turns in this work) and we try to predict the associated transcription performance. Reference (human) transcriptions on Testpred are used to evaluate the quality of the prediction.

3.1. French Broadcast Programs Corpus

The data used in our protocol comes from different broadcast collections in French:

- Subset of Quaero\(^4\) data which contains 41h of broadcast speech from different French radio and television programs on various subjects.
- Data from ETAP\(\) E\(\) [11] project which includes 37h of radio and television programs (mainly spontaneous speech with overlapping speakers).
- Data from ESTER 1 & ESTER 2 [12] containing 111h of transcribed audio, mainly from French and African radio programs (mix of prepared and more spontaneous speech: anchor speech, interviews, reports).
- Data from REPERE [13]: 54 hours of transcribed shows (spontaneous, such as debates) and TV news.

As described in Table 1, the full data contains non spontaneous speech (NS) and spontaneous speech (S). The data used to train our ASR system (Train\(_{\text{Acoustic}}\)) is selected from the non-spontaneous speech style that corresponds mainly to broadcast news. The data used for performance prediction (Train\(_{\text{pred}}\) and Test\(_{\text{pred}}\)) is a mix of both speech styles (S and NS). It is important to mention that shows in Test\(_{\text{pred}}\) data set were unseen in the Train\(_{\text{pred}}\) and vice versa. Moreover, more challenging (high WERs) shows were selected for Test\(_{\text{pred}}\).

</tr>
</tbody>
</table>

Table 1. Distribution of our data set between non spontaneous (NS) and spontaneous (S) styles

Our shows with spontaneous speech logically have a higher WER (from 28.74% to 45.15% according to the program) compared to the shows with non-spontaneous speech (from 12.21% to 25.41% according to the broadcast program\(^3\)). This S/NS division will allow us to compare our performance prediction systems on different types of documents with non spontaneous and spontaneous speech.

3.2. ASR system used

To obtain speech transcripts (ASR outputs) for the prediction model, we built our own French ASR system based on the KALDI toolkit [14] (following a standard Kaldi recipe). A hybrid HMM-DNN system was trained using Train\(_{\text{Acoustic}}\) (100 hours of broadcast news from ESTER, REPERE, ETAPE and Quaero). A 5-gram language model was trained from several French corpora (3323M words in total - from EUbookshop, TED2013, Wit3, GlobalVoices, Gigaword, Europarl-v7, MultiUN, OpenSubtitles2016, DGT, News Commentary, News WMT, LeMonde, Trames, Wikipedia and transcriptions of our Train\(_{\text{Acoustic}}\) dataset) using SRILM toolkit [15]. For the pronunciation model, we used lexical resource BDLEX [16] as well as automatic grapheme-to-phoneme (G2P) transcription to find pronunciation variants of our vocabulary (limited to 80k).

3.3. Evaluation

The LNE-Tools [17] are used to evaluate the ASR performance. Overlapped speech and empty utterances are removed. We obtain 22.29% WER on Train\(_{\text{pred}}\) and 31.20% on Test\(_{\text{pred}}\) (see Table 1). In order to evaluate WER prediction task, we use Mean Absolute Error (MAE) metric defined as:

\[
M A E = \frac{\sum_{i=1}^{N} |W E R_{i}^{\text{Ref}} - W E R_{i}^{\text{Pred}}|}{N}
\]

where \(N\) is the number of units (utterances or files).

We also use Kendall’s rank correlation coefficient \(\tau\) between real and predicted WERS, at the utterance level.

4. ASR PERFORMANCE PREDICTION

4.1. Regression Baseline

An open-source tool for automatic speech recognition quality estimation, TranscRater [5], is used for the baseline regression approach. It requires engineered features to predict the WER performance. These features are extracted for each utterance and are of several types: Part-of-speech (POS) features capture the plausibility of the transcription from a syntactic point of view\(^7\). Language model (LM) features capture the plausibility of the transcription according to a N-gram model (fluency)\(^5\). Lexicon-based (LEX) features are extracted from the ASR lexicon\(^6\). Signal (SIG) features capture the difficulty of transcribing the input signal (general recording conditions, speaker-specific accents)\(^8\).

\(^3\)http://www.quaero.org

\(^4\)http://lia.univ-avignon.fr/chercheurs/bechet/download/lia_phon.v1.2.jul06.tar.gz

\(^5\)Treetagger [18] is used for POS extraction in this study

\(^6\)We train a 5-gram LM on 3323M words text already mentioned

\(^7\)A feature vector containing the frequency of phoneme categories in its pronunciation is defined for each input word

\(^8\)For feature extraction, TranscRater computes 13 MFCC (using Opensmile [19]), their delta, acceleration and log-energy, F0, voicing probability,
This approach, based on engineered features, can be considered as our baseline. One drawback is that its application to new languages requires to find adequate resources, dictionaries and tools which makes the prediction method less flexible. The next sub-section proposes a new (resource-free) prediction approach based on convolutional neural networks (CNNs) where features are learnt during training.

4.2. Convolutional Neural Networks (CNNs)

For WER prediction, we built our model using both Keras and Tensorflow.

For pure textual input, we propose an architecture inspired from [21] (green in Figure 1). Input is an utterance padded to $N$ words (N is set as the length of the longest sentence in our full corpus) presented as a matrix $EMBED$ of size $N \times M$ (M is embedding size - our embeddings are obtained with Word2Vec [22]). The convolution operation involves a filter $w$ which is applied to a segment of $b$ words to produce a new feature. For example, feature $c_i$ is generated from the words $x_{i:i+b-1}$ as:

$$c_i = f(w \cdot x_{i:i+b-1} + b)$$

(2)

Where $b$ is a bias term and $f$ is a non-linear function. This filter is applied to each word segment in the utterance to produce a feature map $c = \{c_1, c_2, \ldots, c_n\}$. Max-pooling [23] then takes the 4 largest values of $c$, which are then averaged. $W$ filters provide a W-sized input to two fully-connected hidden layers (256 and 128) followed respectively by dropout regularization (0.2 and 0.6) before WER prediction.

For signal input, we use the best architecture (ml18) proposed in [10] (colored in red in Figure 1). This is a deep CNN with 17 conv-max-pooling layers followed by global average pooling and three hidden layers (512, 256 and 128 dimensions). A dropout regularization of 0.2 is added between the last two layers (256 and 128). We investigate several inputs to the CNN using Librosa [24]: raw signal, mel-spectrogram or MFCCs.

In order to predict the WER using CNN, we propose two different approaches:

- **CNNSoftmax**: we use Softmax probabilities and an external fixed $WER_{vector}$ to compute $WER_{pred}$. $WER_{vector}$ and Softmax output must have the same dimension. $WER_{pred}$ is then defined as (expectation):

$$WER_{pred} = \sum_{C=1}^{NC} P_{softmax}(C) \cdot WER_{vector}(C)$$

(3)

With NC as total number of classes. In our experiment, we use 6 classes with $WER_{vector}=[0\%, 25\%, 50\%, 75\%, 100\%, 150\%]$.

- **CNNReLU**: after the last FC layer, a ReLU function returning a float value between 0 and $+\infty$ estimates directly $WER_{pred}$.

For joint use of both speech and text, we merge the last hidden layers of both CNN $EMBED$ and CNN $RAW-SIG$ (or $MEL-SPEC$ or $MFCC$) by concatenating and passing them through a new hidden layer before $CNN_{Softmax}$ or $CNN_{ReLU}$ (see dotted lines in the Figure 1) and we train the full network similarly.

Fig. 1. Architecture of our CNN with text (green) and signal (red) inputs - dotted lines correspond to joint text+signal case

5. EXPERIMENTS AND RESULTS

In this section, Regression and CNN approaches are compared for ASR performance prediction. The Regression uses several engineered features extracted from the ASR output (POS, LEX, LM, SIG) while the CNN is based on features learnt from the ASR output and from the signal only. For the CNN, we randomly select 10% of the Train$_{pred}$ data as a Dev set. 10 different model trainings (cross-validation) with 50 epochs are performed. Training is done with the Adadelta update rule [25] over shuffled mini-batches. We use $MAE$ as both loss function and evaluation metric. After training, we take the model (among 10) that led to the best $MAE$ on Dev set and report its performance on Test$_{pred}$. We investigate several inputs to the CNN:

- **Textual (ASR transcripts) only ($EMBED$)**: input matrix has dimension 296x100 (296 is length of longest ASR hypothesis in our corpus ; 100 is dimension of word embeddings pre-trained on our large text corpus of 3.3G words).

- **Raw signal only ($RAW-SIG$)**: models are trained on six-second speech turns and sampled at 8kHz (to avoid memory issues). Short speech turns (<6s) are padded with zeros. Our input has dimension 48000 x 1.

- **Spectrogram only ($MEL-SPEC$)**: we use same configuration as for raw signal ; we have 96-dimensional vectors (each dimension corresponds to a particular mel-frequency range) extracted every 10ms (analysis window is 25ms). Our input has a dimension 601x96.

- **MFCC features only**: we compute 13 MFCCs every 10ms to provide the CNN network with an input of dimension 601x13.

9https://www.tensorflow.org

10We use filter window sizes $h$ of $[1, 3, 5, 7, 9]$ with 256 filters per size

11The detailed parameters of the filters are given in Figure 1.

12The detailed parameters of the filters are given in Figure 1.
- Joint (textual and signal) inputs (EMBED+RAW-SIG) in that case, we concatenate last hidden layers of both textual and signal inputs (dotted lines of Figure 1).

5.1. Regression (baseline) and CNN performances

The lines Regression of table 2 show results obtained with combined features. We can observe that the best performance is obtained with POS+LEX+LM features (MAE of 22.01%) while adding the SIG does not really improve the model (MAE of 21.99%). This inefficiency of SIG features in regression models was also observed in [5].

Table 2. Regression vs CNN_{softmax} vs CNN_{ReLU} evaluated at utterance level with MAE or τ on Test_{pred}

As for the use of textual features only, CNN_{softmax} and CNN_{ReLU} are equivalent (better MAE but lower τ) than the regression model that uses engineered features. CNN_{softmax} shows better performance than CNN_{ReLU}. Concerning signal features only, ASR performance prediction is a difficult task with all MAE above 25%. However, among the different signal inputs to the CNN, simple MFCCs lead to the best performance both for MAE and τ. While the joint use of textual and signal features did not work for the regression baseline, the combination of inputs for CNNs lead to improved results. The best performance is obtained with CNN_{softmax} (EMBED+RAW-SIG) which outperforms a strong regression baseline (MAE is reduced from 21.99% to 19.24%, while τ is improved from 45.82% to 46.83%). Wilcoxon Signed-Rank Test confirms that the difference is significant with p-value of 4e-08.

5.2. Analysis of predicted WERs

Table 3 shows the predicted WERs (at collection level) for both regression and (best) CNN approaches for different speaking styles (spontaneous and non-spontaneous). Overall, the predicted WER on non spontaneous (NS) and spontaneous (S) speech is very good for the CNN approach. WER_{pred} is at -2.54% on non-spontaneous speech and at -4.84% on spontaneous speech. On the other hand, while efficient on non-spontaneous speech, regression fails to predict performance (-10,11%) on spontaneous speech.

Table 3. Regression vs CNN_{softmax} Predicted WERs (averaged over all utt.) per speaking style (NS/S) on Test_{pred}

Figure 2 analyzes WER prediction at utterance level. It shows the distribution of speech turns according to their real or predicted WER. It is clear that CNN prediction allows to approximate the true WER distribution on Test_{pred} while regression seems to build a gaussian distribution around the mean WER observed on training data. It is also remarkable that the two peaks at WER=0% and WER=100% can be predicted correctly by our CNN model.

6. CONCLUSIONS

This paper presented an evaluation framework for evaluating ASR performance prediction on unseen broadcast programs. CNNs were very efficient encoding both textual (ASR transcript) and signal to predict WER. Future work will be dedicated to the analysis of signal and text embeddings learnt by the CNN and their relation to conditioning factors such as speech style, dialect or noise level.

---

[1] or EMBED+MEL-SPEC or EMBED+MFCC

[2] MAE using single POS, LEX, LM and SIG features is respectively 25.95%, 25.78%, 24.19% and 25.86%
