Abstract.

The fast and efficient elimination of pathogenic bacteria from water, food or biological samples such as blood remains a challenging task. Magnetic isolation of bacteria from complex media holds particular promise for water disinfection and other biotechnological applications employing bacteria. When it comes to infectious diseases such as urinary tract infections, the selective removal of the pathogenic species in complex media such as human serum is also of importance. This issue can only be accomplished by adding pathogen specific targeting sites onto the magnetic nanostructures. In this work, we investigate the potential of 2-nitrodopamine modified magnetic particles anchored on reduced graphene oxide (rGO) nanocomposites for rapid capture and efficient elimination of *E. coli* associated with urinary tract infections (UTIs) from water and serum samples. An optimized magnetic nanocarrier achieves a 99.9% capture efficiency even at *E. coli* concentrations of 1×10^1 cfu mL⁻¹ in 30 min. In addition, functionalization of the nanostructures with poly(ethylene glycol) modified pyrene units and anti-fimbrial *E. coli* antibodies allowed specific elimination of *E. coli* UTI89 from serum samples. Irradiation of the *E. coli* loaded nanocomposite with a near-infrared laser results in the total ablation of the captured pathogens. This method can be flexibly modified

for any other pathogenic bacteria, depending on the antibodies used, and might be an interesting alternative material for a magnetic-based body fluid purification approach.

1. Introduction

Elimination of bacteria from water, food or in clinical settings is still a challenging task. The strategies for bacteria isolation and/or ablation from solutions are currently based on the removal of bacteria via membranes and filters using size discrimination approaches^{1,2} as well as nanostructure based systems, which allow the removal of bacteria from solutions through interaction with the particle surface as well as the ablation of pathogens due to the intrinsic antibacterial properties of these nanostructures.^{3–8} This last system requires strong, efficient and selective binding of the pathogen to the nanostructures. In this regard, magnetic separation techniques based on magnetic nanostructures allow for easy removal of bacteria from different media via a contactless and harmless external magnet.^{4–6,8–16} In addition to the magnetic properties, the high surface/volume ratio of magnetic particles offers more contact surface area for binding pathogen ligands and subsequent capture of pathogens. The size of these particles is typically 2 orders of magnitude smaller than a bacterium, which permits the attachment of multiple particles onto a bacterial cell making magnetic-mediated separation much easier. The removal efficiency of bacteria using magnetic nanoparticles remains however rather low. These systems are also not highly effective in removing ultralow bacteria concentrations ($<1 \times 10^2$ cfu mL⁻¹) due to unspecific interactions with other molecules and substances present next to bacteria, limiting their practical applications. More advanced particle systems, easily separated from water, that exhibit limited nonspecific interactions and are target specific with high loading capacity at high and low bacteria concentrations would be a great advantage.

In this work, we demonstrate that some of the mentioned limitations of magnetic nanoparticles can be overcome through hybridization of nitrodopamine coated magnetic particles (MP_{ND}) onto anti-fouling reduced graphene oxide (rGO) nanosheets ([Fig. 1](#)). This novel magnetic nanocomposite material combines several features: (a) a rGO/MP_{ND} based matrix offering large surface area for effective binding of bacteria, (b) good magnetic properties for the removal of bacteria, (c) decreased non-specific interaction with serum proteins due to the presence of poly(ethylene glycol) functionalized pyrene units (pyrene-PEG), (d) target-specificity towards type-1 fimbriae carrying *E. coli* such as uropathogenic ones due to the integration of anti-fimbrial *E. coli* antibodies, and (d) photothermal properties which allow the eliminated pathogens to be ablated on the matrix.

Fig. 1 Schematic illustration of the fabrication of magnetic nanoheaters for pathogen isolation together with their different advantages.

2. Experimental

1.1. Materials

Hydrazine monohydrate, chitosan, dopamine hydrochloride, sodium nitrite (NaNO_2), sulfuric acid (H_2SO_4), hydrochloric acid (HCl), dichloromethane (CH_2Cl_2), iron(II) chloride tetrahydrate ($\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$), iron(III) chloride hexahydrate ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$), ammonium hydroxide (NH_4OH), O-(2-aminoethyl)-O'-(2-methylethyl)heptaethylene glycol ($\geq 90\%$, $\text{NH}_2\text{-PEG}_8\text{-N}_3$), dichloromethane ($\geq 99.8\%$, CH_2Cl_2), N,N'-disuccinimidyl carbonate ($\geq 95.0\%$, DSC), 1-pyrenecarboxylic acid (97%, Pyr-COOH) and triethylamine ($\geq 99.5\%$, TEA) were obtained from Sigma-Aldrich. Milli-Q water (18 M Ω) was used for all experiments. All reagents and solvents were used without further purification.

Graphene oxide (GO) powder was purchased from Graphenea, Spain.

Serum samples were kindly provided by the CHU, Lille.

Anti-fimbrial antibodies were obtained by immunizing serum from rats with purified fimbriae, which were delipidated and purified on an HiFliQ ProteinA affinity chromatography column (CliniSciences) and eluted at 1 mg mL $^{-1}$ concentration in sodium citrate buffer at pH 5.6.

Three kinds of bacteria were used: the Gram-negative wild type *E. coli* UTI89 (UTI89 WT) and an *E. coli* UTI89 strain lacking type-1 fimbriae (UTI89 Δ fim), and the Gram-positive *Staphylococcus aureus*.

Synthesis of 2-nitrodopamine. 2-Nitrodopamine was synthesized according to [ref. 17](#). Dopamine hydrochloride (1.90 g, 10 mmol) and sodium nitrite (1.52 g, 22 mmol) were dissolved in water (25 mL) and cooled to 0 °C. Sulfuric acid (17.4 mmol in 10 mL of water) was added slowly to the mixture, and a yellow precipitate was formed. After stirring at room temperature overnight, the precipitate was filtered and recrystallized from water to give the product as a hemisulfate salt. Yield 1.9 g (77%). ^1H NMR (DMSO- d_6 , 300 MHz, ppm): 3.10 (br s, 4H, CH_2CH_2), 6.85 (s, 1H), 7.47 (s, 1H).

Synthesis of N-(26-azido-3,6,9,12,15,18,21,24-octaoxahehexacosyl)pyrene-1-carboxamide (pyrene-PEG). Pyrene-PEG was synthesized as reported earlier by our group.¹⁸ Briefly, 1-pyrenecarboxylic acid (100 mg, 0.41 mmol) and DSC (125 mg, 0.49 mmol) were dissolved in anhydrous CH_2Cl_2 (15 mL). To this solution, TEA (68 μL , 0.49 mmol) and $\text{NH}_2\text{-PEG}_8\text{-N}_3$ (214 mg, 0.49 mmol) dissolved in CH_2Cl_2 (2 mL) were slowly added under stirring. The resulting mixture was kept under stirring overnight at room temperature. Then the solvent was evaporated under vacuum. The crude product was dissolved in CH_2Cl_2 (6 mL), washed with 5% HCl aqueous solution (5 mL, twice) and H_2O (5 mL, twice), and dried over MgSO_4 . The residue was purified by silica gel column chromatography using CH_2Cl_2 and the product was isolated as a viscous pale yellow oil; yield = 135 mg, 50%; ^1H NMR (300 MHz, CDCl_3) δ 8.63 (d, 1H, $J = 9$ Hz, py), 8.3–8.0 (m, 8H, py), 7.06 (bt, 1H, $J = 4.3$ Hz, $-\text{NH}-$), 3.9–3.3 (m, 36H, PEG); ^{13}C NMR (75 MHz, CDCl_3) δ 128.6, 127.2, 126.3, 125.8, 125.7, 124.9, 124.7, 124.5, 124.4, 70.8–69.6, 50.7, 40.1; FT-IR: 717, 763, 820, 852, 948, 1039, 1104, 1181, 1248, 1289, 1328, 1348, 1455, 1532, 1602, 1648, 2104, 2867 cm^{-1} .

2.2. Preparation of 2-nitrodopamine modified magnetic particles (MP_{ND})

Magnetic particles (MP) were prepared as reported previously.¹⁹ $\text{FeCl}_2 \cdot 4\text{H}_2\text{O}$ (0.34 g, 1.7 mmol) and $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ (0.95 g, 3.5 mmol) were dissolved in deaerated water (20 mL) and subsequently added to a nitrogen-protected three-necked flask under sonication. The resulting mixture was heated at 50 °C for 30 min. Then concentrated ammonium hydroxide (2 mL) was added dropwise and kept at 50 °C for 30 min. The system was finally cooled to room temperature and the solid product was isolated via a non-uniform magnetic field generated by a Nd–Fe–B permanent magnet. The resulting Fe_3O_4 particles (MPs) were washed six times with Milli-Q water to remove unreacted chemicals and then stored in water.

A water dispersion of bare MPs (10 mg mL^{-1} , 1 mL) was mixed with 2-nitrodopamine (20 mg) and sonicated for 1 h at room temperature. The formed magnetic particles (MP_{ND}) were isolated by means of a magnet and purified through six consecutive wash/precipitation cycles with water to ensure complete removal of unreacted dopamine. The precipitate was dried in an oven at 50 °C.

2.3. Integration of MP_{ND} onto reduced graphene oxide (rGO)

Reduced graphene oxide (rGO) was prepared from GO precursor using hydrazine reduction. Briefly, to 5 mL of GO aqueous suspension (0.5 mg mL⁻¹) was added hydrazine hydrate (0.50 mL, 32.1 mM) and heated in an oil bath at 100 °C for 24 h over which the reduced GO gradually precipitated out of the solution. The product was isolated by filtration over a PVDF membrane with a 0.45 µm pore size, washed copiously with water (5 × 20 mL) and methanol (5 × 20 mL) and dried in an oven at 100 °C overnight.

To a solution of rGO (0.5 mg mL⁻¹) was added an aqueous solution of MP_{ND} (0.5 mg mL⁻¹) corresponding to a ratio of 1/1 and sonicated for 90 min. The formed rGO/MP_{ND} nanostructures were isolated by means of a magnet and purified through six consecutive wash/precipitation cycles with water. The precipitate was dried in an oven at 50 °C.

2.4. Functionalization of rGO/MP_{ND} with pyrene-PEG

The rGO/MP_{ND} nanostructures (500 µg mL⁻¹) were mixed with pyrene-PEG solution (5 mM) and the suspensions were stirred for 1 h at room temperature. All samples were isolated by means of a magnet and purified through six consecutive wash/precipitation cycles with water.

2.5. Covalent linking of anti-fimbrial antibody onto pyrene-PEG-rGO/MP_{ND}

Anti-fimbrial antibody immobilization onto rGO–MP_{ND} nanostructures was achieved by carbodiimide crosslinking chemistry. Briefly, the rGO/MP_{ND} nanocomposite (500 µg mL⁻¹) was mixed with a 100 times diluted antibody solution of 1 mg mL⁻¹ in PBS at pH = 7.4 containing EDC·HCl (25 mM) and NHS (25 mM). The reaction was left to proceed at 4 °C for 2 h under agitation, followed by magnetic extraction and PBS washing to remove weakly adsorbed antibodies. The particles were stored in PBS buffer at 4 °C before use.

2.6. Quantification of amino groups by a modified Kaiser test

Primary amine groups were quantified using a modified photometric assay.²⁰ Briefly, the MP_{ND} particles (500 µg mL⁻¹) were dissolved in 1 mL of Milli-Q water. To this suspension was added 1 mL of the buffer solution (36 g of sodium acetate were dissolved in 6.9 mL of acetic acid and filled with Milli-Q water up to a volume of 100 mL) and then sonicated for 15 min. After that, 1 mL of KCN solution (2 mL of 0.03 M KCN solution was diluted to a volume of 100 mL with pyridine) and 1 mL of phenol solution (80 g of phenol were dissolved in 20 mL of ethanol) were added and the suspension was heated at 120 °C for 10 min; 1 mL of ninhydrin solution (5 g of ninhydrin was dissolved in 100 mL of ethanol) was added and heated for another 10 min. After the solution was cooled to room temperature, 5 mL of ethanol was added (60%) and the absorbance was recorded at 570 nm.

2.6. Instrumentation

NMR spectra were recorded with a Bruker Advance 300 MHz spectrometer using deuterated chloroform as the lock and TMS as an internal standard.

Thin layer chromatography (TLC) was carried out using pre-coated aluminium backed silica TLC plates (Alugram® SIL G/UV₂₅₄, Macherey-Nagel) which were visualized using ultraviolet light. Column chromatography was performed on Sigma-Aldrich® silica gel 60 (pore size 60 Å, 230–400 mesh particle size) without applied pressure.

Reversed phase – high performance liquid chromatography (RP-HPLC) analyses were realized on a Shimadzu LC2010-HT (Shimadzu, Tokyo, Japan). A 5 µm C4 QS Uptisphere® 300 Å, 250 × 4.6 mm column (Interchim, Montluçon, France) was used as the analytical column. The column was heated to 40 °C. The mobile phase was a mixture of eluent A (trifluoroacetic acid 0.05% in H₂O) and eluent B (trifluoroacetic acid 0.05% in CH₃CN) at a flow rate of 1 mL min⁻¹. The linear gradient was 0 to 80% of eluent B in 30 min and the detection was performed at 215 and 254 nm after the injection of 40 µL into the column.

High resolution transmission electron microscopy (HR-TEM) analysis of the prepared samples was carried out by using an FEI, TECNAI G2 F20 instrument operated at an accelerated voltage of 300 kV ($C_s = 0.6$ mm, resolution 1.7 Å). For the TEM analysis, the sample was prepared by drop casting 10 µL of the dispersed solution of 1 mg of material in 5 mL of isopropyl alcohol over a carbon coated 200 mesh Cu grid. The catalyst drop cast Cu grid was dried and the prepared sample was used for imaging purposes.

Absorption spectra were recorded using a Perkin Elmer Lambda UV-Vis 950 spectrophotometer in a 1 cm quartz cuvette. The wavelength range was 200–1200 nm.

Fourier transform infrared (FTIR) spectra were recorded using a ThermoScientific FTIR instrument (Nicolet 8700) at a resolution of 4 cm⁻¹. Dried samples (1 mg) were mixed with KBr powder (100 mg) in an agate mortar. The mixture was pressed into a pellet under 10 tons load for 2–4 min, and the spectrum was recorded immediately. Sixteen accumulative scans were collected. The signal from a pure KBr pellet was subtracted as the background.

Zeta-potential measurements were performed using a zeta-sizer nano-ZS (Malvern Instruments Inc. Worcestershire, UK). The samples were diluted to 10 µg mL⁻¹ and measured in Milli-Q water at different pH values.

N₂ adsorption–desorption data were obtained using a Quantachrom SI Micromeritics apparatus, and the isotherms were evaluated with the Barrett–Joyner–Halenda method to determine the surface area, pore size and distribution.

Magnetic properties were determined using an MPMS-XL SQUID magnetometer. The magnetization loops M(H) were measured at 300 K by sweeping the applied magnetic field between 20 kOe and –20 kOe. Thermal variation of magnetization was measured using the zero-field-cooled (ZFC) procedure, for which the sample is first cooled down to 5 K in the absence of an applied magnetic field, and then magnetization is measured during the warming of the sample up to 400 K, with an applied magnetic field of 80 Oe.

2.7. Measurement of the photothermal effect

All irradiations were performed in standard 24 well plates. A 980 nm continuous wave laser (Gbox model, Fournier Medical Solution, France) was used for the photothermal experiments.

This laser was injected into a 400 µm core fiber and placed around 3 cm away from the bottom of the wells. The reported laser power densities take this distance into account. The temperature changes were captured using an infrared camera (Thermovision A40) and treated using ThermaCam Researcher Pro 2.9 software.

2.8. Bacterial growth conditions

E. coli UTI89 wild-type strain, UTI 89 Δfim (without fim operon) and *S. aureus* cultures were grown on an LB agar plate upon inoculation overnight in Luria–Bertani (LB) broth at 37 °C with moderate shaking (200 rpm). Upon 50-fold dilution, incubation was prolonged until the OD₆₀₀ had reached 0.5 equivalent to 1 × 10⁹ cells mL⁻¹ (cfu). The bacteria were re-suspended in PBS (10 mM) and adjusted to the required concentration.

2.9. Bacteria isolation

The bacterial suspensions were diluted to the desired concentration (1 × 10¹ to 1 × 10⁸ cfu mL⁻¹). Magnetic nanostructures of different concentrations (4–10 mg mL⁻¹) were dispersed via ultrasonication (5 min, ultrasonic bath Branson 5800) in PBS (5 mL, 10 mM, pH 7.4). Bacterial suspensions (5 mL) were mixed with the magnetic nanostructures (5 mL) under shaking (200 rpm, 37 °C). After a given time interval, an aliquot was taken periodically to measure the remaining bacterial cell concentration by UV/Vis in solution after magnetic nanostructures had been separated by applying an external magnetic field.

The collection efficiency (E) was calculated according to:

$$E (\%) = \frac{(A_0 - A_t)}{A_0} \times 100$$

where A₀ is the initial OD₆₀₀ and A_t the OD₆₀₀ after cell capture. The capacity (Q, cells per mg) was calculated according to:

$$Q (\text{cells per mg}) = \frac{(A_0 - A_t) \times [E. coli]}{0.1 \times c}$$

where c is the concentration of the particles (mg mL⁻¹) and [E. coli] is the concentration of the pathogen in solution.

2.10. Photothermal treatment of magnetically separated pathogens

The magnetic nanostructures used for the separation of the pathogens were irradiated with a 980 nm continuous wave laser (Gbox model, Fournier Medical Solution, France) for 10 min at 1 W cm⁻² and cell viability assessed by counting the viable bacterial colonies.

2.11. Bacterial cell viability

Following magnetic separation as well as photothermal treatment of the nanostructures, the presence and survival of bacteria were assessed by determining the titer of viable bacteria able

to grow. A 10-fold dilution series of the bacterial solutions in phosphate buffered saline were spotted in 10 μL aliquots on an LB-agar medium. Visual counting of the number of colonies upon overnight incubation at 37 $^{\circ}\text{C}$ allowed the initial and final concentrations of the *E. coli* strain in cfu mL^{-1} to be determined.

2.12. Fluorescence-based cell dead/live assay

The separated bacteria were immediately stained for cell viability assays. The total amount of live and dead bacteria cells was determined using the live/dead BacLight bacterial viability

staining kit (Invitrogen). A 1 : 1 mixture of SYTO 9 nucleic acid stain and propidium iodide (PI) was prepared and 3 μL were added to the separation matrix, mixed thoroughly and incubated at room temperature in the dark for 15 min. 5 μL of the stained bacteria suspension was deposited between a glass slide and a cover slip. The slides were observed using a Leica AF6000 LX fluorescent microscope equipped with an Andor iXon 885 Camera and by using an oil immersion objective (100 $\times$; 1.4 NA objective). The fluorescence signal was acquired using dual band excitation and emission filter sets for green fluorescent protein (GFP) and red fluorescent protein (mCherry).

3. Results and discussion

3.1. Fabrication of magnetic reduced graphene oxide nanosheets

Our approach is based on the pre-synthesis of magnetic nanoparticles, and their integration into reduced graphene oxide (rGO) nanosheets, followed by functionalization with pyrene-PEG as well as *E. coli* UTI 89 specific anti-fimbrial antibodies ([Fig. 1](#)) to obtain magnetic nanostructures with high and selective bacterial elimination efficiency, which can be used in aqueous solution as well as in more complex media such as serum.

We have shown previously that 2-nitrodopamine is an excellent ligand to stabilize iron oxide particles formed using the co-precipitation reaction of Fe^{2+} and Fe^{3+} in alkaline media.¹⁹ This amine-terminated ligand is indeed known to be a far superior ligand to stabilize magnetic particles than dopamine.^{21–23} The higher oxidation potential of the 2-nitrodopamine ligand implies that nanoparticle surface degradation is diminished, ensuring irreversible binding of the ligands and good stability of the resulting nanostructures. These properties are crucial when using such particles for follow-up reactions and in biomedical applications.²⁴ Furthermore, π – π stacking interaction of the catechol groups with the aromatic network of a rGO might be in addition favorable for the formation of stable nanostructures.

The 2-nitrodopamine coated iron oxide particles were characterized by FTIR ([Fig. 2A](#)) and X-ray photoelectron spectroscopy (XPS) ([Fig. 2B](#)). The FTIR spectrum of the MP_{ND} particles exhibits a band at $\approx 1290\text{ cm}^{-1}$ corresponding to C–O or NO_2 vibration. The band at 1500 cm^{-1}

is due to the C=C vibration of the catechol system, which overlaps with the asymmetric vibrations of NO_2 at about 1548 cm^{-1} . The bands at 2882 and 2920 cm^{-1} are due to CH stretching vibrations of the dopamine ligand. The broad band at 3367 cm^{-1} and the band at 1650 cm^{-1} are ascribed to the stretching and bending mode of primary amines, respectively. The content of nitrogen in the MP_{ND} particles determined by XPS was 3.3 at%, indicating

further that 2-nitrodopamine is bonded to the surface of the magnetic particles. The amino group density was in addition determined using the UV spectroscopic method proposed by Kaiser et al.²⁰ and proposed by Krueger for the analysis of nanoparticles.²⁵ The amount of primary amino groups on the MP_{ND} particles was found to be $45 \pm 11 \text{ nM g}^{-1}$, in accordance with other amino-functionalized magnetic particles.²⁶

Fig. 2 Characterization of MP_{ND}: (A) FTIR spectrum; (B) Fe_{2p} high resolution XPS spectrum; (C) transmission electron microscopy (TEM) and HRTEM analysis (inset: EDAX analysis displaying the different elements present in the sample).

A representative Fe_{2p} core level XPS spectrum is seen in [Fig. 2B](#). The Fe_{2p3/2} region can be deconvoluted into bands at 709.01 and 711.02 eV, indicating the presence of both Fe²⁺ and Fe³⁺ species. The satellite peak at $\approx 717 \text{ eV}$ is a direct evidence for the presence of Fe³⁺ in the form of $\gamma\text{-Fe}_2\text{O}_3$, suggesting that the 2-nitrodopamine coated magnetic particles are partially oxidized.

To get more insight into the structure and morphology of the MP_{ND}, transmission electron microscopy (TEM) analysis was performed by imaging a sample coated Cu grid ([Fig. 2C](#)). The size of the nanoparticles is in the range of 8–10 nm. EDAX analysis displays different elements (Fe, O, C, N) present in the sample in accordance with the chemical structure of the particles. Furthermore, high resolution transmission electron microscopy (HRTEM) analysis was performed to get more information about the sample. The HRTEM image of MP_{ND} displays fringes with a calculated fringe width of 0.283 nm corresponding to the iron oxide nanoparticles. Dynamic light scattering measurements were performed in addition to

determine the hydrodynamic diameter of the particles, which was determined to be 140 ± 50 nm.

The MP_{ND} particles were incorporated into reduced graphene oxide (rGO) by mixing a 1 : 1 ratio and sonicating for 2 h. The FTIR spectra of rGO before and after loading with MP_{ND} particles are displayed in Fig. 3A. The spectrum of rGO is dominated by a band at ~ 1570 cm⁻¹ due to a C=C stretching mode of the aromatic rings. The presence of an O–H stretching vibration band (~ 3430 cm⁻¹) and stretching modes due to other oxygen containing groups implies the incomplete removal of oxygen groups as expected for rGO. The bands at 1734 and 1094 cm⁻¹ correspond to C=O stretching vibration of residual –COOH and C–O functions, respectively. Loading of rGO with MP_{ND} particles results in a comparable FTIR spectrum as for rGO with additional bands at 2882 cm⁻¹ (C–H stretching) and 1233 cm⁻¹ due to symmetric vibrations of NO₂ groups.

Fig. 3 Characterization of rGO/MP_{ND} particles: (A) FTIR spectra of rGO (grey) and rGO/MP_{ND} (black); (B) UV/Vis absorption spectra of MP_{ND} (grey), rGO (black) and rGO/MP_{ND} (blue); (C) TEM image of rGO/MP_{ND}; (D) N₂ adsorption–desorption isotherms for MP_{ND} (black) and rGO/MP_{ND} (blue); (E) photographs of aqueous dispersions of rGO, MP_{ND} and rGO/MP_{ND} (500 µg mL⁻¹); (F) hysteresis curves of MP_{ND} and rGO/MP_{ND}.

The UV-vis spectrum of hydrazine reduced GO (Fig. 3B) displays an optical absorption peak at 273 nm with an absorption tail in the NIR characteristic of rGO. The UV-vis spectrum of the free 2-nitrodopamine ligand exhibits a prominent peak at 352 nm. The UV-vis spectrum of rGO/MP_{ND} nanostructures is comparable to that of rGO and exhibits a broad absorption maximum at 273 nm and an absorption tail until the NIR.

TEM imaging of the rGO/MP_{ND} hybrid reveals the integration of MP_{ND} nanostructures onto the rGO nanosheets (Fig. 3C) with the overall size of the hybrid estimated to be 200 ± 60 nm.

The surface area of the rGO/MP_{ND} hybrid was determined from N₂ adsorption-desorption isotherms as shown in Fig. 3D. The N₂ adsorption-curve of MP_{ND} can be classified as typical type II without a hysteresis loop.²⁷ In the case of rGO/MP_{ND}, the curve is close to type IV with a weak hysteresis loop in the 0.4–1.0 relative pressure range with the specific surface area increased to 81.71 m² g⁻¹. This increased active surface area will be favorable for the efficient removal of pathogens, as confirmed in the following experiments.

Fig. 3E indicates the difference in colloidal stability of a rGO/MP_{ND} hybrid in water compared to rGO. While MP_{ND} particles have good colloidal stability, from the photographs in Fig. 3E it is evident that the stability of aqueous suspensions of rGO is poor. The rGO particles have completely settled on the bottom of the cuvette after 24 h. In the case of the rGO/MP_{ND} hybrid the slightly opaque color indicates that some larger particles seem to be present in the remaining solution, which have not settled after the 24 h period, indicating a good long term colloidal stability.

The saturation magnetization (M_s) curves of MP_{ND} and rGO hybrids were determined (Fig. 3E). The saturation magnetization value for MP_{ND} is ≈ 49 emu g⁻¹ at 250 K. Compared to the room temperature M_s value of bulk Fe₃O₄ (≈ 92 emu g⁻¹), the values of the MP_{ND} particles are lower as expected, due to the mass of 2-nitrodopamine coating.²⁸ The embedding of these nanostructures onto rGO results in a further decrease to ≈ 34 emu g⁻¹ (Fig. 3E). Ferromagnetic behavior with a coercivity of about 280 Oe is observed for both nanostructures in accordance with XPS data showing the partial oxidation of the MP_{ND} particles.

3.2. Capture of bacterial cells

To assess the enrichment effect of rGO/MP_{ND} particles under magnetic field separation, the rGO/MP_{ND} (500 μ g mL⁻¹) was incubated for up to 30 min with *E. coli* and *S. aureus* and then set on a magnet for magnetically driven sedimentation of the nanostructures with bound bacteria. As shown in Fig. 4A, MP_{ND} particles show a removal capacity of $\sim 62\%$ for *E. coli* and $\approx 32\%$ for *S. aureus*. The difference is believed to be due to the different charge states of Gram-positive and Gram-negative pathogens and that of the particles.⁸ At physiological pH, MP_{ND} particles exhibit a positive charge of $\sim 20 \pm 2$ mV, favorable for *E. coli* separation with a negative charge at pH 7 (Fig. 4B). Indeed, these findings were validated by using chitosan coated magnetic particles, MP_{CS} (see the ESI,† Fig. S1A and B). These particles are negatively charged at physiological pH with a pK_a of the MP_{CS} nanostructures of ~ 6.5 and a positive zeta potential only recorded under acidic conditions. The capture efficiency for *E. coli* was strongly decreased on these nanostructures (Fig. S1C, ESI†) and almost absent for *S. aureus*. This underlines that a positive surface potential is helpful for increasing the removal efficiency of pathogens, showing a negative surface potential under physiological conditions.

However, once attached to rGO, the importance of the surface charge of the nanocomposite is masked by the strong interaction of *E. coli* and *S. aureus* with the underlying rGO nanosheets resulting in 100% capture efficiencies for Gram-positive and Gram-negative bacteria (Fig. 4A).

Fig. 4 (A) Removal efficiency of MP_{ND} and rGO/MP_{ND} (500 $\mu\text{g mL}^{-1}$) of *E. coli* and *S. aureus* (1×10^9 cfu mL^{-1}); (B) zeta potential of rGO, MP_{ND}, and rGO/MP_{ND} as a function of solution pH; (C) zeta potential of *E. coli* and *S. aureus* suspensions (1×10^9 cfu mL^{-1}).

The time and concentration dependent capture efficiency of rGO/MP_{ND} are seen in Fig. 5B, showing a nonlinear concentration dependence with complete bacterial removal only reached at higher concentrations. Using 500 $\mu\text{g mL}^{-1}$ of rGO/MP_{ND} resulted in complete bacterial removal in less than 30 min (Fig. 5A). From the SEM image in Fig. 5C, it can be seen that the bacteria are bound to the rGO/MP_{ND} and are partly embedded in the 3-D nanostructure.

Fig. 5 (A) Change in OD₆₀₀ over time as a function of the concentration of rGO/MP_{ND} upon incubation in *E. coli* UTI89 (1×10^9 cfu mL⁻¹); (B) capture efficiency as a function of the concentration of rGO/MP_{ND}; (C) SEM images of rGO/MP_{ND} mediated bacterial isolation; (D) confocal fluorescence images of live and dead bacterial cells after incubation of 500 µg mL⁻¹ rGO/MP_{ND} for 30 min with *E. coli* UTI89 (1×10^9 cfu mL⁻¹) and subsequent staining with SYTOP 9 (green, alive) and PI (red, dead); (E) photothermal heating curve of rGO/MP_{ND} (500 µg mL⁻¹) under NIR illumination at 1 W cm⁻² in distilled water (1 mL).

Graphene based matrices are reported for their strong antibacterial properties.²⁹ A fluorescence-based cell live/dead assay was used to investigate the removal mechanism at hand. [Fig. 5C](#) shows an overlap of the fluorescence images after staining with SYTO9 and propidium iodide (PI). SYTO9 is a dye which enters through the bacterial membrane and colors in green both living and dead bacteria, while PI staining indicates dead bacteria due to damaged cell wall membranes and gives a red fluorescent color. A significant amount of green-stained cells is observed, and bacteria eliminated by rGO/MP_{ND} are partially viable. To ablate totally the captured pathogens, the photothermal properties of rGO/MP_{ND} in the near-infrared (NIR) were examined. NIR photo-thermal treatment (PTT) is known for its deep penetration into tissue and in combination with rGO nanosheets is suitable for photo thermal ablation of pathogens.^{1,5,29–32} The effective light-to-heat conversion capability of rGO causes irreversible damage to bacterial cells and thus represents an efficient antibacterial treatment approach. Irradiation of rGO/MP_{ND} with a continuous laser at 980 nm for several minutes at a laser power of 1 W cm⁻² results in a temperature increase for distilled water from 20 ± 2 °C to 75 ± 2 °C due to the photothermal heating effect ([Fig. 5D](#)). Irradiation of the bacteria loaded rGO/MP_{ND} matrix for 10 min resulted thus in total ablation of all the bacterial cells.

3.3. Isolation efficiency for pathogen concentrations $<1 \times 10^4$ cfu mL⁻¹

Next to the quantitative evaluation of the nanocarrier's isolation efficiency of highly concentrated pathogens solutions, analysis of the capture capabilities of bacterial suspensions ranging from 1×10^1 to 1×10^4 cfu mL⁻¹ is of utmost importance as the infectious doses of highly virulent pathogens are often $<1 \times 10^1$ cfu mL⁻¹. The classical plate counting method was employed here to validate the removal capacity. The photos of plate counting for *E. coli* and *S. aureus* are depicted in [Fig. 6](#). The counted colony number of the original bacterial solution (control) is significantly different from the counted colony numbers of the solution after incubation for 30 min with rGO–MP_{ND} (500 µg mL⁻¹) and magnetic separation. The capture efficiency of rGO–MP_{ND} remains excellent even at ultralow bacterial concentrations for *E. coli* and *S. aureus* alike.

Fig. 6 Capture and separation efficiency of rGO/MP_{ND} for *E. coli*. Photos of plate cultures before and after treatment with rGO/MP_{ND} (500 µg mL⁻¹) for 30 min.

3.4. Specific removal of pathogenic *E. coli* UTI89

When it comes to infectious diseases, the selective removal of pathogenic species in complex media such as human serum is important. This issue can only be accomplished by adding pathogen specific targeting sites onto rGO/MP_{ND}. For some time our group has been interested in the development of inhibitors^{33,34} and treatments³⁵ for virulent strains of *E. coli* associated with urinary tract infections (UTIs). Among the targets that have been identified for the development of anti-adhesive strategies are type 1 fimbriae, which constitute major virulence factors produced by *E. coli*.³⁶ Type 1 fimbriae are filamentous proteinaceous organelles that are distributed over the entire surface of the bacterium. To achieve selective bacteria elimination, antibodies against the major pilin protein FimA of the *E. coli* UTI89 type-1 fimbriae were covalently anchored to rGO/MP_{ND} (Fig. 1) using the free –NH₂ groups of the 2-nitrodopamine coating of the magnetic particles. To avoid non-specific interaction with bacteria, the modified nanostructures were immersed into a solution of pyrene-PEG (Fig. 1), rendering the matrix anti-fouling. We used an azide modified pyrene-PEG as it allowed us to validate its integration using XPS (Fig. 7A). The high-resolution N_{1s} XPS spectrum of the rGO/MP_{ND} nanostructure modified with pyrene-PEG-N₃ and anti-fimbrial antibodies reveals the azido function incorporation by the presence of signals at 405.2 (Ar–N=N⁺=N⁻) as reported for other N₃-modified interfaces,³⁷ with the band at 401.9 eV assigned to Ar–N=N⁺=N⁻ and the –NH–C=O linkage of the pyrene-PEG and of the anti-fimbrial linkage. The band at 399 eV is due to the presence of unreacted primary NH₂ groups on the MP_{ND} particles and of the anti-fimbrial antibodies.

Fig. 7 (A) N_{1s} high resolution XPS core level spectrum of azide terminated pyrene-PEG and anti-fimbrial modified rGO/MP_{ND}; (B) photos of plate cultures of the original solution of *E. coli* UTI89 and *E. coli* Δfim at 1×10^4 cfu mL⁻¹ after treatment with rGO/MP_{ND} (500 μg mL⁻¹) for 30 min, (C) specific isolation of *E. coli* UTI89 over *E. coli* Δfim from human serum samples spiked with 1×10^8 cfu mL⁻¹ and 1×10^2 cfu mL⁻¹ pathogens.

The capability of these nanostructures for the selective capturing of *E. coli* UTI89 was investigated further. As seen from the photos of plate counting assays (Fig. 7B) for wild type *E. coli* UTI89 and an *E. coli* UTI89 strain lacking type-1 fimbriae (UTI89 Δfim), the complete removal of *E. coli* UTI89 is achieved, while none of the non-fimbriated *E. coli* were eliminated magnetically by the matrix.

The excellent results prompted us to investigate rGO/MP_{ND} nanocarriers for the removal of bacteria from contaminated serum samples. For this, serum samples spiked with 1×10^4 cfu mL⁻¹ or 1×10^2 cfu mL⁻¹ *E. coli* UTI89 or *E. coli* Δfim were exposed to rGO-MP_{ND} (500 μg mL⁻¹) for 30 min before being magnetically separated. As seen in Fig. 7C, excellent capture efficiency could be achieved even in serum indicating an excellent enrichment capability of pyrene-PEG and anti-fimbrial modified rGO/MP_{ND} even in serum.

4. Conclusions

In summary, this study demonstrates the theranostic potential of anti-fimbrial modified magnetic rGO nanocomposites for a magnetic-separation based body fluid purification approach of *E. coli* UTI89. Owing to the large surface area of rGO and the magnetic properties of the integrated 2-nitrodopamine modified magnetic particles, the nanocomposite can rapidly capture bacteria, which can then be separated by an external magnetic field. Integration of *E. coli* UTI89 specific anti-fimbrial antibodies as well as anti-fouling pyrene-PEG enabled the selective capturing of uropathogenic *E. coli* at low and high concentration levels. Furthermore, photothermal treatment of the *E. coli* captured nanocomposite results in a complete ablation of the eliminated pathogens. While the azido groups of the pyrene-PEG in this work have only been used as an XPS marker, in the future different “clickable” functional ligands can be easily integrated onto these magnetic nanocomposites which will open up further means of bacterial strain differentiation and will allow the addition of further antibacterial properties onto the matrix. We thus believe that this novel multi-functional pathogen capturing matrix provides an attractive avenue for pathogen decontamination and other biomedical purposes due to high efficiency even in complex media such as serum. While the therapeutic efficiency of *E. coli* UTI89 removal remains to be demonstrated in the clinic, the proposed approach is expected to help rapid cleaning of bodily fluids in a fast and selective manner.
