Abstract. In the framework of the Chemistry-Aerosol Mediterranean Experiment, a measurement site was set up at a remote site (Ersa) on Corsica Island in the northwestern Mediterranean Sea. Measurement campaigns performed during the summers of 2012 and 2013 showed high organic aerosol concentrations, mostly from biogenic origin. This work aims to represent the organic aerosol concentrations and properties (oxidation state and hydrophilicity) using the air-quality model Polyphemus with a surrogate approach for secondary organic aerosol (SOA) formation. Biogenic precursors are isoprene, monoterpenes and sesquiterpenes. In this work, the following model oxidation products of monoterpenes are added: (i) a carboxylic acid (MBTCA) to represent multi-generation oxidation products in the low-NOx regime, (ii) organic nitrate chemistry and (iii) extremely low-volatility organic compounds (ELVOCs) formed by ozonolysis. The model shows good agreement of measurements of organic concentrations for both 2012 and 2013 summer campaigns. The modelled oxidation property and hydrophilic organic carbon properties of the organic aerosols also agree reasonably well with the measurements. The influence of the different chemical processes added to the model on the oxidation level of organics is studied. Measured and simulated water-soluble organic carbon (WSOC) concentrations show that even at a remote site next to the sea, about 64 % of the organic carbon is soluble. The concentrations of WSOC vary with the origins of the air masses and the composition of organic aerosols. The marine organic emissions only contribute to a few percent of the organic mass in PM1, with maxima above the sea.

1 Introduction

The Mediterranean region is considered as one of the most prominent regions to be detrimentally impacted by climate and air composition changes over both southern Europe and northern Africa. Organic aerosols (OA) account for about 20–50 % of the fine aerosol mass at continental mid-latitudes (Saxena and Hildemann, 1996) and as high as 90 % in tropical forest areas (Kanakidou et al., 2005; Jimenez et al., 2009). They contribute to more than 50 % of EU-regulated PM2.5 concentrations in Europe (Putaud et al., 2004). OA affect both climate and human health. They influence the radiation budget by mostly scattering sunlight resulting in negative direct radiative forcing (Fuzzi et al., 2006; Lin et al., 2014).
Moreover, hydrophilic OA can act as a cloud condensation nuclei and hence modify cloud microphysical properties and lifetime. In terms of health effects, OA toxicity is linked to the oxidative stress which is induced by the reactive oxygen species. The oxidative potential may differ for the different organic precursors (Rattanavaraha et al., 2011; Jiang et al., 2016; Tuet et al., 2017).

OA are usually classified either as primary (POA) or secondary (SOA). POA are directly emitted in the atmosphere, often as intermediate/semivolatile organic compounds (I/S-VOCs), which partition between the gas and the particle phases (Robinson et al., 2007). The gas phase of I/S-VOC is missing from emission inventories (Couvidat et al., 2012; Kim et al., 2016). SOA are produced through chemical oxidation of volatile organic compounds (VOCs) and I/S-VOCs and through condensation of I/S-VOCs.

A large fraction of emitted VOCs is biogenic, especially in the western Mediterranean in summer, when solar radiation is high. Biogenic emissions may age and form SOA as they are transported through different environments (Hayes et al., 2015). Using aerosol mass spectrometer (AMS) measurements performed in an urban area in southern France (Mar- seille) and positive matrix factorisation techniques, El Had- dad et al. (2011, 2013) attributed 80% of the organic aerosol mass to biogenic secondary organic aerosols (BSOA) and near 40% of the BSOA to monoterpene oxidation products. These high biogenic concentrations in an urban area may be partly explained by the influence of anthropogenic emissions on biogenic SOA formation (Carlton et al., 2010; Hoyle et al., 2011; Sartelet et al., 2012).

Similar results were obtained through measurement campaigns in the Barcelona region (Spain), where Minguillón et al. (2011, 2016) have found a prevalence of non-fossil organic aerosol sources in remote and urban environments and clear evidence of biogenic VOC oxidation products and biogenic SOA formation under anthropogenic stressors.

The ChArMEx (Chemistry and Aerosol Mediterranean Experiment: http://charmex.lsce.ipsl.fr) project has organised several summer campaigns to study atmospheric chemistry and its impacts in the western Mediterranean region. The TRAQA (Transport et Qualité de l’Air) campaign was set up in summer 2012 to study the transport and impact of continental air on atmospheric pollution over the basin (Sič et al., 2016). The ADRIMED (Aerosol Direct Radiative Impact in the Mediterranean; Mallet et al. (2016)) campaign was set up in June–July 2013 to assess the radiative impact of aerosols, while the SAF-MED (Secondary Aerosol Formation in the MEDiterranean) campaign was set up in July–early August 2013 to understand and characterise the concentrations and properties of organic aerosols in the western Mediterranean and to figure out the origins of the high concentrations observed outside urban areas. Intensive ground-based in situ measurements were performed during the summer of 2013, while airborne measurements were performed during the summers 2013 and 2014 (Di Biagio et al., 2015; Freney et al., 2017). In agreement with the observations of El Haddad et al. (2013) in Marseille on the French Mediterranea coast, the ground-based in situ measurements performed at the remote site of Ersa on Cape Corsica, the northern tip of Corsica Island (southeast of continental France) showed that OA are mostly from biogenic origin. However, as over urban areas, anthropogenic emissions from shipping or pollution plumes from European big cities may influence biogenic SOA formation (Sartelet et al., 2012).

The VOC biogenic precursors of SOA are isoprene, monoterpenes (MT) and sesquiterpenes. Although sesquiterpenes emission factors are lower than those of isoprene and MT over Europe, their SOA yields are high because of their low saturation vapour pressures (Jaoui et al., 2013). For MT, first-generation oxidation products, such as pinonaldehyde, pinic and pinonic acids contribute to the formation of SOA, although their contributions may be low (Praplan et al., 2015). For α-pinene, further-generation oxidation steps may lead to the formation of very low-volatility products, such as the tricarboxylic acid 3-methyl-1,2,3-butanoxytricarboxylic acid (MBTCA; Müller et al., 2012; Kristensen et al., 2014) and oligomeric compounds. Ehn et al. (2014) and Kris- tensen et al. (2014) showed that highly oxidised organic compounds are formed in the early stages of the oxidation of MT. Rissanen et al. (2015) proposed a mechanistic description of these extremely low-volatility organic compounds (ELVOCs) formation from the most atmospherically abundant biogenic monoterpenes, such as α-pinene and limonene. These ELVOCs have been observed during both chamber and in situ measurements in Germany (Mutzel et al., 2015). Several studies showed the importance of nighttime SOA formation from MT via nitrate radical oxidation, resulting in the formation of organic nitrates (Pye et al., 2015; Bean and Ruiz, 2016; Xu et al., 2015; Nah et al., 2016). Pye et al. (2010) showed the importance of reactive nitrogen and pointed out the fact that organic nitrate accounts for more than a half of the monoterpene oxidation products in the particle phase over the US.

For isoprene, in low-NOx environments, recent studies have focused on the formation of isoprene epoxydiols (IEPOX) in acidic aerosols (Surratt et al., 2010; Couvidat et al., 2013b). However, using AMS measurements, particle-phase IEPOX was not observed during the ChArMEx campaign over an isoprene-emitting forest in the south of France, suggesting it might have formed organosulfates (Freney et al., 2017). Several studies also showed the importance of non-IEPOX pathway for isoprene oxidation in low-NOx environment (Krechmer et al., 2015; Liu et al., 2016). Although ELVOCs may also form from isoprene oxidation, the yields may be low (Jokinen et al., 2015).

OA can also be emitted from the sea because of phytoplankton activity; according to O’Dowd et al. (2004), OA from marine origin can contribute considerably to OA concentrations, especially near the biologically productive waters. Recently derived parameterisations (Gantt et al., 2012;
Schwier et al., 2015) relate the organic fraction of sea-salt emissions to the seawater chlorophyll a (chl a) concentrations. However, the contribution of these species to the organic budget over the Mediterranean Sea is not clear.

SOA modelling has undergone significant progress over the past few years due to the rapid increase of experimental data on SOA yields and molecular chemical composition resulting from the oxidation of a variety of VOC and I/S-VOC. SOA models used in mesoscale models can be grouped into two major categories: (1) models based on an empirical representation of SOA formation and (2) models based on a mechanistic representation of SOA formation. Models of the first category include the widely used two-compound Odum approach (Odum et al., 1996), the more recent volatility basis set (VBS) approach (Donahue et al., 2006, 2011) or the multi-generational oxidation model (Jathar et al., 2015). Models of the second category use experimental data on the molecular composition of SOA and represent the formation of SOA using surrogate molecules with representative physicochemical properties (Pun et al., 2006; Bessagnet et al., 2008; Carlton et al., 2010; Couvidat et al., 2012).

The surrogate approach differentiates low-NOx and high-NOx regimes. The gas–particle partitioning may include both absorption into hydrophobic organic particles and dissolution into aqueous particles and take into account some of the complexity involved in OA partitioning (such as non-ideality, multi-phase partitioning). Although these two categories of models are fundamentally different in their initial design (empirical vs. mechanistic), they aim to describe the same processes. Furthermore, they tend to converge as they continue to be developed and refined. For example, I/S-VOCs from anthropogenic emissions, which are usually specified by volatility classes, can be included in a mechanistic model (Albriet et al., 2010; Couvidat et al., 2013a); also, the VBS scheme can take into account the oxidative state of SOA (Jimenez et al., 2009), in particular its elemental O/C ratio (Donahue et al., 2011; Jathar et al., 2015). The recently developed 1.5-VBS (Koo et al., 2014) assigned a molecular structure to VBS products. Both the mechanistic and empirical approaches are scientifically valid and complementary; as shown by Kim et al. (2011a), the most important aspect of an SOA model is its comprehensiveness in terms of the precursors and processes being treated (completeness of the precursor VOC list, importance of low-NOx vs. high-NOx regimes, treatment of hydrophilic properties of the surrogates) rather than its fundamental design. Cholakian et al. (2017) study how the VBS approach can be used to represent the formation of SOA over the western Mediterranean and point out the importance of taking into account fragmentation and formation of nonvolatile SOA in this framework.

This paper aims to investigate the chemical processes and surrogates that need to be taken into account in the mechanistic representation of SOA to reproduce the concentrations and properties of the observed biogenic SOA at the Ersa supersite in Corsica. The mechanistic representation included in the air-quality model Polyphemus (Couvidat et al., 2012) is modified by including recent research progress on monoterpenes SOA formation (ELVOC, MBTCA, organic nitrate). The influence of primary marine organic emissions is also studied. A further evaluation of the model by comparison to airborne measurements is presented in Freney et al. (2017).

The paper is structured as follows. Section 2 presents the air-quality model used and the improvements made in the mechanistic representation. Section 3 details the model input data sets and the measurement data. Section 4 compares the concentrations and the properties of OA to measurements, as well as the influence of the different chemical processes added to the model. Finally, Sect. 5 studies the impact of the biological activity of the Mediterranean Sea on OA concentrations.

2 Model description

2.1 General features

In order to simulate aerosol formation over the western Mediterranean, the Polair3d/Polyphemus air-quality model is used (Mallet and Sportisse, 2005). The numerical algorithms used for transport and the parameterisations used for dry and wet depositions are detailed in Sartelet et al. (2007). Gas-phase chemistry is modelled with the carbon bond 05 mechanism (CB05) (Yarwood et al., 2005). Different reactions are added to CB05 to model the formation of semivolatile organic compounds from five classes of SOA precursors (intermediate and semivolatile organic compounds of anthropogenic emissions, aromatic compounds, isoprene, monoterpenes and sesquiterpenes) (Kim et al., 2011b; Couvidat et al., 2012). For these classes of precursors, which include a great number of species, only a few surrogates are used to represent all the species.

As detailed in Couvidat and Seigneur (2011), isoprene may form tetroils and methyl dihydroxy dihydroperoxide under low NOx, and methyl glyceric acids and organic nitrates under high NOx. Oxidation of isoprene by the nitrate radical NO3 is also modelled.

For monoterpenes and sesquiterpenes, the oxidation scheme is based on Pun et al. (2006). Humulene is used to represent all sesquiterpenes. For monoterpenes, three precursors are used: API (for α-pinene and sabinene), BPI (for β-pinene and δ3-carene) and LIM (for limonene and other monoterpenes and terpenoids). Depending on the NOx regimes, three surrogates are formed: pinonaldehyde, norpinic acid and pinic acid. Although a simple parameterisation was developed to represent the oligomerisation of pinonaldehyde as a function of pH in Couvidat et al. (2012), it is not used here because its influence on SOA formation is not clear. As detailed in Couvidat et al. (2012), I/S-VOC emissions are emitted as three primary surrogates of differ-
but it is supposed to be hydrophobic. Under high-NO$_x$ conditions, the surrogate is not identified, but it is supposed to be hydrophobic. Under high-NO$_x$ conditions, the surrogates formed are two benzoic acids (methyl nitrobenzoic acid and methyl hydroxy benzoic acid). Table 1 describes the five classes of precursors used to represent the SOA formation and the surrogates used.

The SIze REsolved Aerosol Model (SIREAM; Debry et al., 2007) is used for simulating the dynamics of the aerosol size distribution by coagulation and condensation/evaporation. SIREAM uses a sectional approach and the aerosol distribution is described here using 20 sections of bound diameters: 0.01, 0.0141, 0.0199, 0.0281, 0.0398, 0.0562, 0.0794, 0.1121, 0.1585, 0.2512, 0.3981, 0.6310, 1.0, 1.2589, 1.5849, 1.9953, 2.5119, 3.5481, 5.0119, 7.0795 and 10.0 µm. The ageing of each primary surrogate is represented through a single oxidation step, without NO$_x$ dependance, to produce a secondary surrogate of lower volatility (log(C$^*$) = −2.4, −0.064, 1.5 respectively) but higher molecular weight. For aromatic compounds, toluene and xylene are used as surrogate precursors. The precursors react with OH to form radicals that may then react differently under low-NO$_x$ and high-NO$_x$ conditions. Under low-NO$_x$ conditions, the surrogate is not identified, but it is supposed to be hydrophobic. Under high-NO$_x$ conditions, the surrogates formed are two benzoic acids (methyl nitrobenzoic acid and methyl hydroxy benzoic acid). Table 1 describes the five classes of precursors used to represent the SOA formation and the surrogates used.

2.2 ELVOCs

Ehn et al. (2014) and Kristensen et al. (2014) showed that extremely low-volatility hydrophobic molecules of high molecular weight form at the early stage of oxidation of the monoterpenes α-pinene and limonene by ozone. In the model, a unique gaseous precursor representing α-pinene and limonene is used for ELVOC formation. The ELVOC yield is assumed to be 11%, i.e. close to the average of the yields of α-pinene and limonene according to Ehn et al. (2014). Jokinen et al. (2015) suggested lower yields (Table 2). In this paper, sensitivity simulations with a lower bound of 3% and an upper bound of 18% are also conducted.

Relying on known chemistry and experimental findings, Ehn et al. (2014) and Rissanen et al. (2015) provided a formation pathway from monoterpenes to ELVOCs through the autoxidation process (Crounse et al., 2013).

The ozonolysis reaction leads to the formation of peroxy radicals (RO$_2$), which are the starting point of ELVOC formation. These radicals undergo a fairly rapid (~1 s$^{-1}$) sequential intramolecular H-atom shift followed by O$_2$ addition leading to the formation of highly oxygenated peroxy radicals ($R_{ELVOC}$O$_2$). This O$_2$ addition leads not only to an increase in molecular weight but also to a decrease in the radical volatilities. Rissanen et al. (2015) investigated these reactions including the different steps, possible isomerisation as well as the most likely chemical pathways leading to an enrichment of peroxy radicals by oxygen. The oxygen-centred peroxy radical intermediates are internally rearranged by intramolecular hydrogen shift reactions, enabling more oxygen molecules to attach to the carbon backbone. Simultaneously, the sequential H-shift mechanism competes with reactions between peroxy radicals, NO and HO$_2$. Subsequently, the termination reactions lead to the formation of ELVOCs. ELVOC monomers and dimers are formed through reactions of $R_{ELVOC}$O$_2$ with RO$_2$ and HO$_2$. Following Ehn et al. (2014), the reactions for the ozonolysis of α-pinene
and limonene (MT), as well as the kinetic constants used in the model (Table A1), are included in the model as detailed in Appendix A. The formation of organic nitrate from \( R_{\text{ELVOC}}O_2 \) peroxy radicals is not considered in the model, as the reactions proposed by Ehn et al. (2014) led to negligible concentrations.

The aerosol species introduced in the model for ELVOC formation and their properties are detailed in Table 3. The enthalpy of vaporisation of the monomer and dimer is set to 50 KJ mol\(^{-1}\) (Svendby et al., 2008), and the saturation vapour pressure is assumed to be very low and is taken equal to \( 10^{-14} \) torr at 298 K.

### 2.3 Organic nitrates formation mechanism

Organic nitrates are formed where biogenic VOCs and anthropogenic \( \text{NO}_x \) sources interact (Pye et al., 2015; Xu et al., 2015; Bean and Ruiz, 2016; Nah et al., 2016). We used here the parameterisation of Pye et al. (2015) to account for the formation of organic nitrate compounds from the oxidation by OH and \( \text{NO}_3 \) of MT. The oxidation of MT by OH leads to the formation of a peroxy radical TERPRO\(_2\), and the oxidation by \( \text{NO}_3 \) leads to the formation of TERPNRO\(_2\) (nighttime chemistry). The peroxy radicals TERPRO\(_2\) may react with NO to form organic nitrate with a molar yield of 20.1%, while the oxidation of TERPNRO\(_2\) leads to higher yields. The reactions, as well as the kinetic constants (Table B1) are described in Appendix B.

Following Pye et al. (2015), the estimated vapour pressure of the condensing organic nitrate species is assumed to be \( 5 \times 10^{-6} \) torr (Fry et al., 2009), and the enthalpy of vaporisation is taken as 40 KJ mol\(^{-1}\). The aerosol species (orgNIT) introduced in the model and its properties are summarised in Table 3. The organic nitrate is assumed to be hydrophobic (Liu et al., 2012).

### 2.4 MBTCA: an aging product of the pinonic acid

It was shown in a set of studies that ozonolysis and OH-initiated reactions of terpenes produce organic acids (Hatakeyama et al., 1991; Hoffmann et al., 1997; Warnke et al., 2006). Szmigielski et al. (2007) identified MBTCA (3-methyl-1,2,3-butanetricarboxylic acid) as the most relevant organic acid for atmospheric SOA. It is produced by the OH oxidation of pinonic acid, which is itself produced by the OH oxidation of \( \alpha \)-pinene. The OH oxidation of pinonic acid to form MBTCA is added to the model with a kinetic constant \( k = 9.0 \times 10^{-12} \) cm\(^3\) s\(^{-1}\) (Jaoui and Kamens, 2001) and a yield of 0.0061 (Müller et al., 2012). Following Couvidat et al. (2012), MBTCA is supposed to be hydrophilic, with a OM / OC ratio of 2.125 (Table 3).

3.1.2 Meteorological data

3.1.3 Emissions

Anthropogenic emissions are generated using the EDGAR-HTAP_V2 inventory for 2010 (http://edgar.jrc.ec.europa.eu/htap_v2/). The monthly and daily temporal distribution for the different activity sectors are obtained from GENEMIS (1994) and the hourly temporal distribution from Sartet et al. (2012). Following Sartet et al. (2007), NO\(_x\) emissions are split in mass into 90\% of NO, 9.2\% of NO\(_2\) and 0.8\% of HONO. SO\(_2\) emissions are split into 98\% of SO\(_2\) and 2\% of H\(_2\)SO\(_4\) (in molar concentrations). For emissions of non-methane volatile organic compounds, the speciation of Passant (2002) is used. PM\(_{2.5}\) primary particle emissions are speciated into dust, POA and black carbon. POA are assumed to be the particle phase of I/S-VOC. Total I/S-VOC emissions (gas and particle phases) are estimated as detailed in Couvidat et al. (2012) by multiplying POA by a fixed value and by assigning them to species of different volatilities. The volatility distribution is kept the same for all emission sectors, although more detailed volatility distributions could be defined following the work of May et al. (2013a, b); Jathar et al. (2014). In this study, the ratio I/S-VOC / POA is set to 2.5 (Kim et al., 2016) and (Zhu et al., 2016). Setting the ratio of semivolatile organic carbon to POA to 1, i.e. ignoring I/S-VOC, has little impact on the organic concentrations, as shown in Fig. 2. Particles of diameters higher than 2.5 \(\mu\)m are all speciated into dust. Biogenic emissions are estimated with the Model of Emissions of Gases and Aerosols from Nature (MEGAN; Guenther et al., 2006). Over the Mediterranean domain, during the period of the 2013 summer simulation, the average emissions of sesquiterpenes, monoterpenes and isoprene are 0.001, 0.019 and 0.024 \(\mu\)g m\(^{-2}\) s\(^{-1}\) respectively.

Hence, compared to isoprene and monoterpane emissions, the sesquiterpene emissions are lower by a factor of 95.8 and 94.7\% respectively.

Sea-salt emissions are parameterised following Jaeglé et al. (2011), who modelled the generation of sea salt by the evaporation of sea spray produced by bursting bubbles during whitecap formations due to the friction with surface wind. The emitted sea-salt mass is assumed to be made of 30.61\% sodium (Seinfeld and Pandis, 2006), 25.40\% chloride and 4.22\% sulfate following results from measurements in mesocosms made in Corsica in July 2012 (Schwier et al., 2015). The organic fraction of sea-salt emissions is not taken into account in the simulation presented here. However, it is estimated in Sect. 5, where the contribution of organic sea-salt emissions to organic concentrations is assessed.

3.2 Measured data

The model results are compared to observational data from ChArMEx campaigns during the summers of 2012 and 2013. The station is located at the red point in Fig. 1. The measurement site is located at Ersa (42°58’N, 9°21.8’E), on a ridge at an altitude of about 530 m above the sea level, and has an unimpeded view of the sea over \(\sim 300^\circ\) from the SSW to

Figure 2. Relative difference (%) of OM\(_1\) concentrations simulated using the emission ratio I/S-VOC / POA = 2.5 and 1.
SSE (Mallet et al., 2016). The ground-based comparisons are performed by comparing the measured concentrations to the simulated ones using the concentrations of the model cell the closest to the station. The central coordinates of this cell at which concentrations are computed are 42°52′N, 9°22′30″E, which is very close to the station and with a similar altitude above sea level (494 m). Cholakian et al. (2017) studied the difficulty to correctly represent in a model the orography of Ersa site, which is a cape at the northern edge of Corsica. They concluded that the representativeness error is about 10% for organic aerosols.

To evaluate the organic concentrations and oxidation properties, an ACSM (aerosol chemical speciation monitor) was used to measure the real-time chemical composition and mass loading of aerosols with aerodynamic diameters between 70 and 1000 nm (sulfate, nitrate, ammonium, chloride and organic compounds), between 8 June and 2 July 2012 and between 6 June and 3 August 2013. The ratio OM/OC and the oxidation state of organics are estimated using the ACSM measurements following Kroll et al. (2011).

Other instruments were deployed in 2013 to evaluate the organic properties: a PILS-TOC-UV to estimate the watersoluble fraction of organics (Sciare et al., 2011) between 14 July and 5 August 2013 and a high-volume quartz filter sampling DIGITEL for 14C measurements in organics between 16 and 30 July 2013.

A direct evaluation of the simulated concentrations of ELVOCs or organic nitrates cannot be done because they were not measured during the campaigns.

3.3 Model–measurements comparison method

To evaluate a model, several approaches and performance scores can be used. Here, we compare model simulation results to measurements using a set of performance statistical indicators: the simulated mean (T), the root mean square error (RMSE), the correlation coefficient, the mean fractional bias (MFB) and the mean fractional error (MFE). They are defined in Table C1 of Appendix C. Based on the MFB and the MFE, Boylan and Russell (2006) proposed a performance and a goal evaluation criteria as detailed in Table C2 of Appendix C.

4 Comparison to measurements

The concentrations of organic aerosols are compared to measurements for the summers of 2012 and 2013. The origins of organic aerosols (fossil vs. non-fossil), and their properties (oxidation state, hydrophilic properties) are compared to the measurements performed during the intensive measurement period of the summer 2013. In the simulation presented here, the ELVOC yield is assumed to be 11%, as detailed in Sect. 2.2. Two sensitivity simulations are performed using a lower bound yield (3%) and an upper bound yield (18%).

In Appendix D, similarly to what is presented in this section for the reference simulation, the sensitivity simulations are compared to each other and to the measurements in terms of the mass of OM1, the organic aerosol composition and the OM/OC and O/C ratios.

4.1 Organic concentrations

The comparisons of the measured and modelled temporal profiles of the concentration of the submicron organic mass (OM1) at Ersa are shown in Fig. 3 for the two summer campaigns of 2012 and 2013. The model shows satisfactory results at Ersa station, as shown by the statistics in Table 4. Both the goal and the performance criteria of Boylan and Russell (2006) are verified for both years (MFB < 30% and MFE < 50%). The overall concentration of OM1 is reasonably well modelled, although it is slightly underestimated 2.58 (3.71) µg m⁻³ against 2.89 (4.14) µg m⁻³ in the measurements for 2013 (2012). Overall, the model reproduces very well the peaks and troughs of OM1 concentrations in both 2012 and 2013 with the exception of a few days in late June–early July 2013. This period is a period with air trajectories passing over France (Arndt et al., 2017), during which aging processes of biogenic compounds may be particularly important with formation of aged hydrophilic SOA. In the model, this process would lead to the formation of aged carboxylic acids, with MBTCA used as surrogate. However, the simulated concentration is low because the yield used is very low (it corresponds to the yield of MBTCA only).

4.2 Sources of OA

In both 2012 (6 June to 8 July) and 2013 (6 June to 10 August), the modelled organic mass is dominated essentially by biogenic particles (Fig. 4). They represent 77 and 75% of the organic mass. In the model, for comparisons to the 14C measurements, the biogenic-origin organic compounds are assumed to be non-fossil, and the anthropogenic-origin organic compounds are assumed to be fossil. Although in winter, some of the anthropogenic-origin organic compounds may originate from wood combustion (residential heating) and be non-fossil, we assume that the fraction of anthropogenic-origin organic compounds from residential heating is low in summer. The simulated OC is computed by dividing the modelled organic mass of each model surrogate by the OM/OC ratio of the surrogate.

During the period when 14C measurements were performed (16 to 30 July), 75% of the modelled organic mass is biogenic, in agreement with the 14C measurements, which estimated that 85% is non-fossil. The measured and simulated means are 2.5 and 1.9 µgC m⁻³, respectively, for non-fossil OC, and 0.5 and 0.6 µgC m⁻³, respectively, for fossil OC. Although fossil OC is well modelled, non-fossil OC is slightly underestimated between 16 and 30 July.
The modelled average chemical compositions of OM$_1$ at Ersa during the summers of 2012 and 2013 are presented in Fig. 4. The chemical composition is very similar between the years 2012 and 2013.

Monoterpene oxidation products including ELVOCs and organic nitrate represent a large part of biogenic aerosols (about 48% in 2012 and 2013). ELVOCs and organic nitrate are abundant. ELVOCs represent 10% of OM$_1$ in 2012 and 15% in 2013. Organic nitrate represent 24% of the organic mass in 2012 and 20% in 2013. The route to organic particulate nitrate may essentially (but not exclusively) be active during the night as NO$_3$ efficiently photolyses during the day and the production yields are more important during the night, and higher organic-nitrate concentrations are observed at night (Fig. 5).

MBTCA, an oxidation product of MT, represents a tiny portion of OM$_1$, following the very low molar yield used. After MT, the most important biogenic precursor is isoprene; its oxidation products represent about 20% of OM$_1$ in 2012 and 16% in 2013. Although sesquiterpenes emissions are lower than isoprene and monoterpene emissions, their oxidation products represent about 10% of OM$_1$. Anthropogenic oxidation products represent about 22 and 25% of OM$_1$ in 2012 and 2013 respectively. Most of anthropogenic oxidation products originate from intermediate and semivolatile organic emissions (about 19% of OM$_1$; they are referred to as anthropogenic SOA and POA in Fig. 4) and from aromatic oxidation products (3 to 5% of OM$_1$).

### 4.3 Oxidation state of organics

The level of oxidation of ambient organic aerosols is assessed by the ratio of organic matter to organic carbon (OM/OC) and the ratio of oxygen to carbon ratio (O/C). OM is made up of many different molecular structures and it may include not only particulate organic carbon but also oxygen, hydrogen, nitrogen and/or sulfate. Hence, a high OM/OC ratio indicates a high degree of oxidation of the organic aerosols and probably a high degree of hygroscopicity (Jimenez et al., 2009). There is a variety of methods that have been used to calculate OM/OC ratio as reported by Xing et al. (2013). In our case, the ambient OM/OC ratio is calculated by weighting the ratio (OM/OC)$_i$ of each surrogate species $i$ by the relative mass of the surrogate:

$$\text{OM/OC} = \sum_{i=1}^{N_{\text{esp}}} (\text{OM/OC})_i \times \text{OM}_i / \text{OM}$$

where $N_{\text{esp}}$ is the number of surrogate species. The ratio (OM/OC)$_i$ of the surrogate species $i$ depends only on the molecular structure of the species and the number of carbons in the molecule. The O/C ratio allows for the degree of oxygenation of the organics to also be considered.

The measured and simulated temporal evolutions of both OM/OC and O/C ratios for submicron organic aerosols are shown in Fig. 6 during the whole summer 2013 campaign period. The contributions from ELVOCs, organic nitrate and MBTCA are highlighted.

Relying on the measured values, the organic species over Ersa are highly oxidised and oxygenated. In fact, the measured value of the OM/OC ratio (2.43) is higher than the value of 2.1 suggested by Turpin and Lim (2001) for a rural site like Kern Refuge (US). The measured O/C ratio is 0.99. In agreement with the measurements, all simulations show a relatively stable OM/OC ratio and O/C ratio during the simulated period.

Without taking into account the ELVOCs, MBTCA and organic nitrate species, the model strongly underestimates both...
the OM / OC ratio and the O / C ratio. This is because of the absence of highly oxidized species in the model, as all the other modelled organic compounds with non-negligible mass tend to have low OM / OC and O / C ratios.

Taking into account the formation of ELVOCs leads to improvements in the predicted oxidation state of aerosols: the OM / OC ratio (O / C) changes from 1.57 to 1.89 (0.51 to 0.65), although the monomer and dimer ELVOCs only represent 15.7 % of the OM mass.

MBTCA has a low impact on the organics oxidation level, despite its high OM / OC ratio, because it constitutes only a tiny part of the OM mass (0.2 %).

Taking into account organic nitrate leads to an improvement of both ratios. The OM / OC increases from 1.89 to 2.18 and the O / C ratio increases from 0.65 to 0.73.

A possible way to explain the underestimation of the OM / OC ratio (2.17 simulated against 2.43 measured) and the O / C ratio (0.73 simulated and 0.99 measured) is to take into account the formation of organosulfate. As both organic and sulfate are the major components of aerosols at Ersa (Nicolas, 2013), there may be formation of organosulfate, as suggested by the transmission electron microscopy measurements of Freney et al. (2017) in the south of France.

The measurements performed at Ersa show a good correlation between sulfate and organic OM concentrations, with a linear regression coefficient of 0.64. In agreement with the measurements, the simulated concentrations of sulfate and organics are also well correlated with a linear regression coefficient of 0.71. Although the formation of organosulfate is not modelled here, the modelled correlation is high because both sulfate and organics are formed by oxidation of precursors, and oxidant concentrations largely depend on meteorological variables, such as temperature and dilution within a variable mixing layer. Furthermore, a large part of biogenic SOA is hydrophilic and therefore higher condensation of sulfate enhances their partitioning into the particulate phase, as the mass of the aqueous phase increases through the condensation of sulfate (Couvidat and Sartelet, 2015).

In laboratory, the formation of organosulfate was observed from the uptake of monoterpene oxidation products (pinonaldehyde) on acidic sulfate aerosols (Liggio and Li, 2006; Surratt et al., 2008), from the uptake of ELVOC (Mutzel et al., 2015) and from the uptake of isoprene oxidation products (Liggio et al., 2005; Nguyen et al., 2014). Isoprene SOA may be formed via the reactive uptake of IEPOX, a second-generation oxidation product of isoprene, in the presence of hydrated sulfate (Surratt et al., 2010; Couvidat et al., 2013b; Nguyen et al., 2014). Using AMS measurements, Hu et al. (2015) estimated that IEPOX-OA makes a large fraction of the OA (between 17 to 36 % in the US) outside urban areas, in agreement with Budisulistiorini et al. (2015). In regions where aerosols are acidic, IEPOX-derived OA may be strongly dependent on the sulfate concentration, which acts as nucleophile and facilitates the ring-opening reaction of IEPOX and organosulfate formation (Nguyen et al., 2014; Xu et al., 2015).
In order to take into account the influence of the formation of organosulfates on OA properties, the surrogate products of the model are modified. As Mediterranean aerosol composition displays large concentrations of sulfate, isoprene oxidation products may lead to the formation of organosulfate. In the model, the components formed from the low-NOx oxidation of isoprene are BiPER and BiDER. The surrogate BiPER is supposed to be a methyl dihydroxy dihydroperoxide. Although BiDER is not identified, it is assumed to have the properties of a methyl tetrol (Couvidat and Seigneur, 2011).

If we assumed that this compound has the same properties as a sulfate ester of formula C_6H_{11}O_3SO_4, the ratios OM/OC and O/C increase to get closer to measurements (Fig. 6). In fact, the average OM/OC ratio (O/C) increases from 2.18 (0.73) to 2.37 (0.84), which compares very well with the average measured ratios (2.43 for OM/OC and 0.99 for O/C). Even though the ratio O/C still seems to be slightly underestimated, the discrepancies may be explained by uncertainties in the measurements. Measurements performed at the same place between 10 July and 6 August with a high-resolution time-of-flight AMS shown an average OM/OC ratio of 2.34 (±0.14) and an average O/C ratio 0.92 (±0.11).

### 4.4 Water-soluble organics

Water-soluble organics constitute a major fraction of organic compounds. On average between 15 and 31 July 2013, submicron water-soluble organic carbon (WSOC) represents 64% of the organic carbon in the measurements and 46% in the model. WSOC concentrations are well modelled on average (the measured mean is 1.0 µgC m^{-3} and the modelled mean is 0.9 µgC m^{-3}). Figure 7 shows the daily concentrations of WSOC in the model and according to the measurements. Although the WSOC concentrations are well modelled between 21 and 31 July, they are underestimated between 15 and 20 July. These differences between the periods in the ability of the model to represent WSOC concentrations may be linked to differences in the organic aerosol composition and in the origins of air masses. This is illustrated by the comparison of 16 and 30 July. WSOC concentrations are underestimated on 16 July but are well modelled on 30 July. 16 July is characterised by low/calm winds in a time when 30 July is characterised by winds from southeast France. Figure 8 shows the chemical composition of modelled OM_1 for both days. On 30 July, hydrophilic oxidation products of isoprene constitute most of the mass: they represent 26% of the concentrations against 9% on 16 July. However, organic nitrate (from monoterpene oxidation) represents as much as 35% of OM_1 concentrations on 16 July, against only about 10% on 30 July, because the low winds of 16 July probably enhance the influence of NO_x emissions from ships on pollutant concentrations.

Although this organic nitrate is assumed to be hydrophobic, it may have undergone hydrolysis resulting in nitric acid and nonvolatile secondary organic aerosol that may change the hydrophilicity of organics and the organic composition, as detailed in Pye et al. (2015).
Figure 8. Simulated chemical composition of OM$_1$ on 16 July (a) and on 30 July 2013 (b).

Figure 9. (a) Temporal average of chl$_a$ in sea surface in units of mg m$^{-3}$ during the summer of 2013 (from 6 June to 3 August). (b) Organic mass fraction of emitted sea-spray aerosols of diameters between 0.01 and 0.1585 µm. (c) Relative difference (%) in the concentrations of OM$_1$ between the base simulation and the simulation including organic sea-salt emissions.

5 Impact of the biological activity of the Mediterranean Sea

According to O’Dowd et al. (2004), organic aerosols of marine origin can contribute to organic OM$_1$ concentrations especially near biologically productive waters. Particles of diameters larger than 1 µm tend to contain mostly inorganic compounds, and the fraction of organic increases with decreasing diameter for particles of diameters smaller than 1 µm (O’Dowd et al., 2004; Schwier et al., 2015).

Several studies found a correlation between the organic mass fraction of sea-spray aerosol (OM$_{SSA}$) and the concentrations of oceanic parameters like chl$_a$, which is used as a proxy for biological activity and related ocean chemistry (O’Dowd et al., 2008; Gantt et al., 2011; Schwier et al., 2015). Several parameterisations exist to estimate the fraction of organics in primary marine aerosols. Whereas in the parameterisation of Schwier et al. (2015), which is designed for Aitken mode aerosols, the organic fraction depends not only on chl$_a$ but also on the 10 m wind speed and the particle diameter in Gantt et al. (2012). OM$_{SSA}$ decreases with increasing 10 m wind speed, because for strong wind speeds, bubbles are not enough enriched by organic matter due to the wave breaking. Concerning the size dependence, Gantt et al. (2012) showed that the maximum organic fraction in the Aitken and accumulation modes is about 80 to 90 %, while the fraction is less than 2 % in the coarse mode.

The concentrations of the chl$_a$ are obtained from monthly averaged MODIS/AQUA satellite data (https://oceandata.sci.gsfc.nasa.gov/MODIS-Aqua/L3SMF/, Hu et al., 2012), with a spatial resolution of 4 km $\times$ 4 km. They are shown in Fig. 9a.

Values are low, typical of oligotrophic conditions that characterise stratified surface Mediterranean waters in summer. The highest chl$_a$ concentrations are recorded around the coastal zones meaning shallow water, places where sea currents bring cold waters with plants and nutrients from sea floor or brought from the rivers to the surface due to the rising slope of the sea floor.

Far from the coasts, the chl$_a$ is more or less uniform (less than 0.2 mg m$^{-3}$). The chl$_a$ temporal average near Ersa is 0.14 mg m$^{-3}$.

The emitted organic mass fraction of sea salt is shown in Fig. 9b using the parameterisation of Gantt et al. (2012) for aerosols of diameters between 0.01 and 0.1585 µm. The organic fraction map has almost the same spatial distribution as the chl$_a$ map. The fraction of marine organic emissions is higher near the shores of the continent. The temporal average of emitted OM$_{SSA}$ near Ersa is detailed in Table 5 for aerosols of different sizes. As expected, the organic fraction...
During the summer 2013, the added surrogates led to a significant increase of mass concentrations: they contributed to 15 % of the OM\textsubscript{1} mass for ELVOC, 20 % for organic nitrate from monoterpene oxidation and 0.2 % for MBTCA. In agreement with \textsuperscript{14}C measurements, most of the organic aerosol is from non-fossil (biogenic) origin. The inclusion in the model of ELVOC and organic nitrate formation greatly improves the modelled oxidation state of particles, as assessed by the OM/OC and O/C ratios. Despite the model improvements, these ratios remain underestimated compared to measurements (2.18 simulated against 2.43 measured for OM/OC and 0.73 simulated against 0.99 measured for O/C). However, the ratios are better modelled by assuming that a surrogate species from isoprene oxidation is an organosulfate (2.37 simulated for OM/OC and 0.84 for O/C), suggesting that further work should focus on a better description of organosulfate formation. Although an organic acid, MBTCA, was introduced as a second-generation product of MT, its yield should be revised to include the formation of several carboxylic acids rather than a single species. Concerning the hydrophilic properties of aerosols, as much as 64 % of organic carbon is soluble. Therefore, taking into account the hydrophilic properties of aerosols is crucial to model the partitioning of aerosols between the gas and particle phases. The average concentration of water soluble organic carbon is relatively well modelled by comparison to measurements performed using a PILS-TOC-UV (with a mean value of 1.0 µgC m\textsuperscript{-3} in the measurements and 0.9 µgC m\textsuperscript{-3} in the model) over the second half of July 2013. Daily comparisons to measurements show that although organic nitrate is assumed hydrophobic here, its hydrolysis should be modelled to better represent the hydrophilic properties of organics. There are other pathways and mechanisms that are not considered in the model, but that may change the concentrations and hydrophilicity of organics (Shrivastava et al., 2017). For example, salting effects (via activity coefficients) are not considered, although inorganics provide a mass onto which hydrophilic organic surrogates may condense. Furthermore, pathways such as the aging chemistry of VOCs and I/S-VOCs from biomass burning (wildfires) and organic cloud processing are not considered. However, these pathways may be relatively low during the studied periods. Marine organic aerosols were added to the model, with a parameterisation depending on chlorophyll \textsubscript{a}, 10 m wind speed and particle diameters. Although the emitted organic fraction is high for particles of small diameters (Aitken and accumulation modes), its contribution to the total organic mass OM\textsubscript{1} is higher for aerosols in the Aitken mode (~ 0.31) than in the accumulation mode (~ 0.22) than in the coarse one (~ 0.01). These simulated organic fractions are consistent with the fraction obtained by the Schwier et al. (2015) parameterisation for the Aitken mode (0.23). They are also consistent with the average fraction of 0.24 found experimentally by Schwier et al. (2015) using pelagic mesocosms in the bay of Calvi (Corsica, France) during the summer of 2012 (an average fraction of 0.24).

A simulation was performed using the organic fraction of primary marine emissions computed with the Gantt et al. (2012) parameterisation, in order to assess the impact of the marine organics on the concentrations of organics OM\textsubscript{1}. The organic emissions are affected to a new species called “SSorg”, which is assumed to be hydrophobic and not very volatile. The properties are detailed in Table 3. The values are assumed to be the same as those taken for methyl nitrobenzoic acid in the model, following the lack of data characterising the properties of these species. Secondary marine OM formation is not taken into account.

Figure 9c shows the relative difference of organic OM\textsubscript{1} concentrations between the base simulation and the simulation including organic sea salt. The contribution of the organic sea-salt emissions to organic OM\textsubscript{1} is small (a few percent at the maximum) and localised above the sea. On average over the marine domain, the organic sea-salt emissions contribute to about 1.8 % of the organic OM\textsubscript{1} concentrations. Despite the larger chl \textsubscript{a} and organic fraction over the Adriatic Sea, the contribution of SSorg to OM\textsubscript{1} concentrations is not as high as the one over the Mediterranean Sea in the south of France. This is due to the fact that the surface wind-driven flux of sea salts over the Adriatic Sea is not as important as over the Mediterranean Sea in the south of France.

### 6 Conclusions

This paper presents comparisons of modelled organic concentrations and properties to surface measurements performed at Ersa (Cape Corsica, France) during the summers of 2012 and 2013. The air-quality model of the Polyphe- m\textsubscript{m}us platform is used with a surrogate approach to model SOA. The previously published surrogate approach is modified to better represent observed OA properties, by taking into account the formation of ELVOCs and organic nitrate from monoterpene oxidation. The concentrations of organic matter compare well to the measurements performed with an ACSM.
is only a few percents at the maximum. Its contribution over the continent is always lower than 1 to 2%.

Appendix A: Formation of ELVOC

The reactions involved in the formation of ELVOCs are

- MT + O$_3$ $\xrightarrow{k_1} \gamma$RO$_2$ - RO$_2$ + (1-$\gamma$)RO$_2$ - R'O$_2$ (AR1)
- R'O$_2$ $\xrightarrow{k_{H/O_2}} \alpha$ - R''O$_2$ (AR2)
- R''O$_2$ $\xrightarrow{k_{H/O_2}} \alpha$ - R$_{elvoc}$O$_2$ (AR3)
- RO$_2$ + R'O$_2$ $\xrightarrow{k_2}$ products (AR4)
- RO$_2$ + NO $\xrightarrow{k_3}$ $\delta$ - RO$_2$ (AR5)
- RO$_2$ + HO$_2$ $\xrightarrow{k_4}$ products (AR6)
- R$_{elvoc}$O$_2$ + RO$_2$ (or HO$_2$) $\xrightarrow{k_5}$ $\beta$ - monomer + (1-$\beta$) - dimer (AR7)
- R$_{elvoc}$O$_2$ + NO $\xrightarrow{k_6}$ $\chi$ - nitrate$_{org}$ + $\phi$ - monomer (AR8)

After numerous combinations, the stoichiometric coefficients of Eq. (AR1) were determined, such as reproducing the observations of Ehn et al. (2014) for both the low-NO$_x$ and high-NO$_x$ regimes (Table A2).

For model validation, comparisons are made to the experiments of Ehn et al. (2014). In the low-NO$_x$ regime, the experiments of Ehn et al. (2014) lasted 45 min and the initial ozone concentration was 80 ppb. In the model, we modified the initial concentration of $\alpha$-pinene from 0 to 11 ppb to reproduce the observations. Figure A1, which shows one-fifth of the ELVOC concentrations as a function of the $\alpha$-pinene reaction rate, reproduces successfully the extended data in Fig. 10 of Ehn et al. (2014). According to Fig. A1, the increase of peroxy radicals has a square root dependence while ELVOC monomers and dimers evolve nearly linearly. Therefore, the total ELVOC concentration has a near-linear dependence on the amount of $\alpha$-pinene reacting with O$_3$ indicative of first-generation oxidation products. These findings are consistent qualitatively and quantitatively with Ehn et al. (2014) measured and modelled results.

In the high-NO$_x$ regime, the experiments of Ehn et al. (2014) also lasted 45 min and the initial ozone and $\alpha$-pinene concentrations were 80 and 5 ppb respectively. The initial NO concentration was changed gradually from 0.3 to 5 ppb. Figure A2, which shows one-fifth of the ELVOC as a function of the RO$_2$ concentration, reproduces successfully the extended data in Fig. 10 of Ehn et al. (2014). While increasing NO concentration, both monomer and dimer concentrations decrease rapidly as expected because a fraction of peroxy radicals is consumed by the NO reaction. Moreover, the dimer concentration decreases rapidly while the monomer concentration decreases more slowly. Simultaneously, the organic nitrate concentration increases with increasing NO.
Appendix B: Formation of organic nitrate

The formation of organic nitrate (orgNIT) from MT is modelled with the following reactions:

\[
\begin{align*}
\text{Terpene} + \text{OH} & \rightarrow k_1 \text{TERPRO}_2 \\
\text{TERPRO}_2 + \text{NO} & \rightarrow k_2 0.201 \text{orgNIT} \\
\text{MT} + \text{NO}_3 & \rightarrow k_3 \text{TERPNRO}_2 \\
\text{TERPNRO}_2 + \text{NO} & \rightarrow k_4 0.688 \text{orgNIT} + \text{products} \\
\text{TERPNRO}_2 + \text{HO}_2 & \rightarrow k_5 \text{orgNIT} + \text{products} \\
\text{TERPNRO}_2 + \text{NO}_3 & \rightarrow k_6 0.422 \text{orgNIT} + \text{products} \\
\text{TERPNRO}_2 + \text{RO}_2 & \rightarrow k_7 (1 - 0.578 \delta) \text{orgNIT} + \text{products}
\end{align*}
\]

where \( \delta = 50\% \)

Appendix C: Statistic indicators and criteria

The statistic indicators used in this paper are described in Table C1. The performance and goal criteria used in this paper are described in Table C2.

Appendix D: Sensitivity to ELVOC yield

The ELVOC yield in the reference simulation is 11%. Two sensitivity simulations are performed, using a lower bound (3%; Jokinen et al., 2015) and a higher bound (18%; Ehn et al., 2014).

The comparison of OM\(_1\) concentrations is shown in Fig. D1 and the statistical evaluation is shown in Table D1. The correlation between the measurements and the simulation is not modified by the ELVOC yield. However, the higher the yield is, the closer to zero the bias is (it decreases from −26 to −7%) and the lower the error MFE. However, the lower RMSE is obtained with a yield of 11% (1.53 µg m\(^{-3}\) with a yield of 11% against 1.54 µg m\(^{-3}\) with a yield of 3% and 1.59 µg m\(^{-3}\) with a yield of 18%).

The simulated composition of OM\(_1\) using ELVOC yields of 3 and 18% are shown in Fig. D2. Using an ELVOC yield of 3% (18%), the ELVOCs represent 4.7% (22.9%) of the OM\(_1\) mass.

The OM/OC and O/C ratios are plotted using the three yields (3, 11 and 18%) in Fig. D3. The simulated means of the two ratios using the three ELVOC yields (3, 11 and 18%) are shown in Table D2. The ratios using the upper bound of ELVOC yields are the closest to the measurements. The OM/OC and O/C ratios may be higher when organosulfate is considered (Sect. 4.3).
Figure D1. Simulated daily concentrations of OM₁ using a molar ELVOC yield of 11% (blue plot, reference simulation), 18% (magenta plot) and 3% (green plot).

Table D1. Statistics of model to measurements comparisons for organic concentrations in particles of diameters lower than 1 µm during the summer campaign of 2013 using an ELVOC molar yield of 3, 11 (reference) and 18%. \( \bar{\tau} \) represents the simulated mean concentrations. The observed mean concentration is \( \bar{\tau} = 2.89 \mu g m^{-3} \).
