A B S T R A C T

Chemical warfare agents are an actual threat and victims' decontamination is a main concern when mass exposure occurs. Skin decontamination with current protocols has been widely documented, as well as surface decontamination. However, considering hair ability to trap chemicals in vapour phase, we investigated hair decontamination after exposure to sulphur mustard simulants methyl salicylate and 2-chloroethyl ethyl sulphide. Four decontamination protocols were tested on hair, combining showering and emergency decontamination (use of Fuller's earth or Reactive Skin Decontamination Lotion RSDL[®]). Both simulants were recovered from hair after treatment, but contents were significantly reduced (42–85% content allowance). Showering alone was the least efficient protocol. Concerning 2-chloroethyl ethyl sulphide, protocols did not display significant differences in decontamination efficacy. For MeS, use of emergency decontaminants significantly increased showering efficacy (10–20% rise), underlining their usefulness before thorough decontamination. Our results highlighted the need to extensively decontaminate hair after chemical exposure. Residual amounts after decontamination are challenging, as their release from hair could lead to health issues.

1. Introduction

Despite international regulation through the Chemical Weapons Convention [1], recent history has shown that military or civilians exposure to chemical warfare agents (CWA) can still occur [2]. Among CWA, sulphur mustard (SM or HD) is one of the most famous as it was massively used during World War I. It is a highly reactive agent which quickly penetrates skin [3] and alkylates numerous molecules, including DNA [4,5]. First symptoms of skin contamination, *i.e.* irritation followed by vesication, usually appear only 30 min to several hours after exposure [6].

Following exposure to CWA, emergency decontamination and

care are of primary importance. Decontamination consists in neutralizing and/or removing the contaminant from the body surface. Emergency decontamination kits such as fuller's earth (FE) and Reactive Skin Decontamination Lotion (RSDL[®]) have been shown to be quite effective on pig skin when used even 45 min following exposure to the nerve agent VX [7]. Thorough decontamination will then consist in disrobing, showering with water containing detergent or soap, rinsing with water, and finally drying [8,9].

Effectiveness of skin decontamination procedures has been largely investigated through the use of *in vitro* and *in vivo* human skin models [10–15], including human volunteers studies involving non-toxic CWA simulants [16,17]. However, wounds, hair or eyes decontamination have been much less studied and is important to consider. Previous studies have shown that following vapour exposure, scalp hair can trap external contaminants such as cocaine

and cannabinoids [18,19] but also the chemical warfare agent simulants methyl salicylate (MeS) [20] and 2-chloroethyl ethyl sulphide (CEES) [21]. To our knowledge, health issues related to chemicals trapping ability of hair and their subsequent decontamination have not been investigated. Indeed, once trapped in hair, chemicals could actually be released and intoxicate more people, including rescuers. As a matter of fact, secondary exposure to sarin has been observed during Tokyo subway attack in 1995 [22–24], highlighting the need for proper decontamination and protection when dealing with chemically contaminated people. Keeping that in mind, it is essential that decontamination procedures take the hair matrix into account, and that efficacy of standard decontamination protocols be evaluated for hair.

In this work, hair locks were exposed to MeS or CEES vapours, then decontaminated with various procedures in order to evaluate their efficacy on hair. These chemicals were selected as SM simulants according to their physicochemical properties. MeS shows similar vapour pressure to SM (see Table 1) and was then chosen to mimic SM's behaviour in vapour phase. Given that octanol/water partition coefficients are similar for both compounds (Table 1), MeS is also expected to behave similarly to SM towards the hair lipid phase. However, as opposed to MeS, the chemical structure and, as a result, electrophilic properties of CEES are similar to that of SM (Table 1). Furthermore, the main interest of using MeS as SM simulant is that it is far less toxic than SM or CEES. Therefore, it can safely be used to test experimental set-up.

Four decontamination procedures were evaluated and compared. They combined emergency decontaminants (FE and RSDL®) and thorough decontamination (shower).

2. Materials and methods

2.1. Chemicals, materials and hair

Methyl salicylate (99% purity), 2-chloroethyl ethyl sulphide (98% purity) and N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA) were purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France). Internal standard (IS) methyl salicylate- d_4 was purchased from Cluzeau Info Labo (Sainte-Foy-la-Grande, France). Suprasolv® dichloromethane (DCM) and acetone were supplied by VWR (Fontenay-sous-Bois, France), as well as Teflon® ribbon used to hang hair locks for exposure.

Standard MeS (1182 $\mu\text{g mL}^{-1}$) and CEES (1605 $\mu\text{g mL}^{-1}$) solutions were freshly prepared in DCM, and calibration solutions were prepared by subsequent dilution of standard solutions. Preparation of spiking IS solution in acetone (58.6 $\mu\text{g mL}^{-1}$) was previously described [20].

One-liter two-neck round-bottom flasks were manufactured by the glasswork service of Aix-Marseille University (Marseille, France).

FE (particle size $90\% \leq 100 \mu\text{m}$) was purchased from Sigma-Aldrich (Saint-Quentin-Fallavier, France). RSDL® kits were obtained from E-Z-EM Canada Inc. (Anjou, Canada). The OpCell® sponge contained in those kits was cut into $2.5 \times 3.5 \text{ cm}$ pieces. Liquid Marseille soap from Le Sérail (Marseille, France) was used for showering experiments. *In vitro* hair showering was performed as already described by Josse and colleagues [28]. Water temperature and flow rate could be modulated from 15 to 50°C, and from 0.1 to 5 L min^{-1} , respectively. Liquid soap concentration was adjustable from 0.2 to 10% (v/v). Absorbing paper (Fouque Chimie, Marseille, France) was used to remove FE from hair and to dry hair after showering.

Natural blond hair was supplied by Sécher-Fesnoux (Chaville, France). Hair samples were prepared as 5-g locks (~30-cm long). In order to avoid hazardous chemicals projections, hair showering was performed in a CaptairPyramid glove box from ErLab (Val-de-Reuil, France) disposed in a fume hood.

2.2. Hair exposure to MeS or CEES

Hair locks were weighed then hung at the top of a 1-L closed two-neck round-bottom flasks. Pure MeS (20 μL i.e. 23.6 mg) or pure CEES (100 μL i.e. 107 mg) was loaded at the bottom of the tank via a lateral neck. After closure, the tank was placed for 2 h in an oven at 40°C in order to speed up the evaporation process.

Control experiments were conducted in the same way. Contaminated hair was extracted just after exposure in order to evaluate initial contamination (initial content Q_0).

2.3. Hair decontamination

After exposure, hair locks were removed from the tank then transferred into a crystallizer. They were subjected to decontamination according to the procedures described in the following sections. Steps combination for each procedure is detailed in Table 2.

During showering, we did not apply any physical cleaning of hair surface, i.e. use of a sponge or flannel, in order to avoid variability due to human action.

2.3.1. Hair powdering with FE

A relatively large amount of FE, i.e. 5 g, was poured on the hair in order to entirely cover them. Then, hair was wiped 5 times from top to bottom by using a cotton pad. This allowed enhancing FE

removal from hair.

2.3.2. RSDL[®] application on hair

RSDL[®] lotion (3 mL) was applied on the top of hair lock and then spread on the entire hair length by using an OpCell[®] sponge fragment (2.5 × 3.5 cm). RSDL[®] was left on hair for 2 min, as recommended for the skin.

2.3.3. Hair showering and drying

Hair showering was performed according to the ORCHIDS protocol, which is recommended for skin decontamination following exposure to CWA [29]. Hair lock was hung on top of the glove box and showered with water at 35°C containing 0.5% soap for 1 min then, after 1 min, with clear water at 35°C for 1 min (“shower” protocol). For “RSDL[®] + rinse” protocol, hair was washed with clear water at 35°C for 30 s. The water flow rate was 4–4.5 L min^{−1}. After showering, hair lock was unhooked and extensively dried with absorbing paper.

2.4. Extraction of chemicals from hair

To extract MeS or CEES from hair, three successive solvent treatments were performed by using 50, 30 and 20 mL dichloromethane (3 × 10 min agitation at 250 rpm for each treatment). Adequate dilution of pooled extracts was made before GC-MS/MS analysis.

2.5. Gas chromatography-tandem mass spectrometry (GC-MS/MS) analysis

MeS extracts were aliquoted to 1 mL and spiked with 10 µL IS solution. Then, 100 µL of spiked extract were transferred out to be enriched with 50 µL BSTFA. They were finally heated at 55°C for 30 min to complete silylation. Derivatized extract were injected (1 µL) and analysed by GC-MS/MS.

CEES extracts were directly injected and quantified with external calibration.

Extracts were analysed by gas chromatography tandem mass spectrometry. 7890A gas chromatograph and 7000 MS from Agilent Technologies, Inc. (Santa Clara, USA) were used to perform GC-MS/MS analyses. Injection, separation and detection parameters have already been published [20]. Monitored transitions to quantify the contaminants are indicated in Table 3.

Linearity over the calibration range was satisfactory ($R^2 > 0.99$). Calibration and control solutions were injected and accepted if

back-calculation accuracies were between 80 and 120%. Otherwise, deviant values were dismissed and corresponding samples prepared from the extracts were injected all over again.

2.6. Decontamination efficacy

In this work, decontamination efficacy (DE) was calculated from the ratio:

$$DE(\%) = \left(\frac{Q_0 - Q_D}{Q_0} \right) \times 100$$

where Q_0 is the average content of MeS or CEES extracted from non-decontaminated hair used as controls ($n = 3$) and Q_D is the content of MeS or CEES extracted from decontaminated hair. Five replicates were performed for each decontamination protocol, and an average DE was calculated.

2.7. Statistical analysis

One-way between subjects ANOVA analyses were performed on decontamination efficacy data by using R software (R Core Team, R: A language and environment for statistical computing, R Foundation for Statistical Computing, Vienna, Austria). The level of significance adopted was p -value < 0.05 ($p < 0.001$: highly significant difference between the groups; $p < 0.01$: very significant difference; $p < 0.05$: significant difference; $p > 0.05$: no significant differences between the groups).

3. Results

3.1. Extraction of MeS or CEES from non-decontaminated hair

Control experiments showed a recovered content of $4.21 \pm 1.38 \mu\text{g mg}^{-1}$ MeS from non-decontaminated hair. This represented a total amount of 21 mg, namely 89% of the liquid challenge. For CEES, $1.41 \pm 0.48 \mu\text{g mg}^{-1}$ was extracted from non-decontaminated hair. It represented a total amount of 7 mg, namely 6.5% of the initial dose.

3.2. Hair decontamination efficacy

3.2.1. MeS

Following decontamination, MeS extracted from hair was very significantly reduced ($p < 0.001$), i.e. by a 2 to 3-fold factor,

whatever the protocol used. DE reached up to 67% when the “RSDL® + rinse” protocol was applied. The “shower” protocol was the least effective (DE value of 42%). Application of FE or RSDL® prior to showering eliminated 52% and 65% of the contamination, respectively.

3.2.2. CEES

Hair decontamination was quite effective towards CEES, as all protocols reduced very significantly ($p < 0.001$) the amount of contaminant. The DE reached up to 85% when FE was used prior to showering. Showering showed 80% DE. The “RSDL® + rinse” and “RSDL® + shower” protocols yielded DE of 73% and 77%, respectively. Nevertheless, there was no significant difference ($p > 0.05$) between the four tested protocols.

3.2.3. Effect of the contaminants on the protocols DE

DE of the four protocols against MeS and CEES are represented on Fig. 1.

The DE of “RSDL® + rinse” and “RSDL® + shower” were similar after hair exposure to MeS or CEES, i.e. about 70–80%. By contrast, when the “FE + shower” or “shower” protocols were applied to hair, the DE was 30–40% higher towards CEES than MeS.

4. Discussion

This study was designed to evaluate the decontamination efficacy of various standard protocols on hair exposed to CWA simulants by using an *in vitro* model. As it is one of the first investigations of hair decontamination, we chose to firstly evaluate existing protocols in order to establish if currently used procedures are efficient against chemically contaminated hair. For this reason, we limited our investigations to showering, FE and RSDL®.

4.1. Hair decontamination efficacy

Hair decontamination after exposure to CWA or surrogates has been scarcely studied. Soo Hoon Eunice and colleagues showed that showering for 10 s with water at 21°C containing a cationic

surfactant only partially decontaminated hair exposed to liquid SM [30]. The maximum decontamination efficacy was 37%. It dropped to 22% when water was used without any detergent. Thus, in this work, hair decontamination efficacy was 2 to 4-fold lower than in our experiments. More recently, Josse *et al.* evaluated hair decontamination 1 hr following liquid contamination with a droplet (10 µL) of the nerve agent VX [28]. They showed that up to 98% of the initial dose could be eliminated by use of emergency decontamination (FE or RSDL®) prior to showering.

In liquid contamination, only a small proportion of the liquid is in direct interaction with a part of the contaminated subject. On the contrary, we can reasonably assume that vapour exposure, as performed in our work, leads to a more important hair surface contamination and better mimics situations for which victims would be exposed to toxic vapours. Our results (Fig. 1) showed that hair decontamination was not 100% effective, whatever the simulant used. For MeS, up to 12 mg was still present in 5 g hair after decontamination. For CEES, we quantified up to 1.9 mg contaminant for the same amount of hair. Considering whole scalp hair on a person and depending on hair length, such residual contamination could still be significant. Residual amount of contaminant might be desorbed and transferred from hair to any surface that would come into contact with it. For SM, the percutaneous median lethal dose LD_{50pc} is about 100 mg kg⁻¹ [25]. For a 70-kg person, it means that 7 g on the skin can cause lethal effects. First irritant and/or incapacitating effects can appear at lower dose, i.e. 12–30 mg min.m⁻³ for vapour exposure [31], or 10 µg cm⁻² for skin contact [32]. Release of trapped toxic from hair, even at the mg or µg level, could thus be health threatening for the contaminated victim and its entourage.

Our results showed that for a given procedure, DE could be agent-dependent. More specifically, the DE of hair showering with soap and water (“shower” protocol) was almost twice greater for CEES than for MeS. This could be explained by the different physicochemical properties displayed by these two agents. In particular, CEES undergoes hydrolysis faster than MeS: half-times in water are respectively 1.4 min [33] and 14.1 days [26]. With protocols including water washing steps, CEES could be significantly hydrolysed, this resulting in a higher elimination rate when compared to MeS.

4.2. Importance of emergency decontamination prior to showering

Showering was shown to be effective for skin decontamination following exposure to SM or MeS [16,29]. In our work, showering alone proved to be the least effective procedure on SM simulant MeS (42% DE), and for CEES (80% DE for showering) there was no significant difference compared to other procedures. Our study did not include hair rubbing while showering but physical action on skin surface (with the use of a flannel for example) proved to increase skin decontamination efficacy by about 20% [34].

Effectiveness of FE and RSDL® for skin decontamination has already been demonstrated [7,10,35]. In these works, FE or RSDL® were shown to significantly lower the extent of injuries and decrease the amount of agents absorbed through the skin. Moreover, work from Rolland and colleagues showed that VX contamination of hairy skin resulted in 19% of the initial dose being trapped in hair [7]. Using FE or RSDL® even 45 min after exposure respectively divided initially absorbed dose in hair by 12 and 108. Our results confirmed the effectiveness of FE or RSDL® for hair decontamination of CEES and MeS. Hair powdering with FE prior to showering increased the decontamination efficacy of showering by about 10% for MeS and 5% for CEES. Similarly to FE, use of RSDL® prior to showering significantly increased the hair decontamination efficacy against MeS by 23%.

Fig. 1. Decontamination efficacy of tested protocols against hair contaminated with MeS (black) or CEES (white).

When they are available, FE or RSDL[®] should then be recommended as emergency decontaminants of skin and hair prior to showering.

4.3. Operational implications

Our results together with those of previous works [7,20,21,28,30] underlined the importance of taking hair into account when victims are exposed to chemicals then decontaminated.

As already demonstrated for VX [28], our results showed that when performed prior to showering, emergency decontamination, e.g. by using FE or RSDL, could significantly increase hair decontamination efficacy of SM simulants. As demonstrated for skin decontamination, our results confirmed that displacing (by adsorptive properties of decontaminants) or neutralizing (by chemical reactive reagents) the contamination plays a critical role in victims' decontamination.

5. Conclusions

Standard decontamination protocols were evaluated *in vitro* on scalp hair exposed to the SM simulants methyl salicylate (MeS) and 2-chloroethyl ethyl sulphide (CEES). Our results showed that emergency decontamination (FE or RSDL[®]) prior to showering was quite effective for hair decontamination. However, decontamination efficacy did not reach 100%. Residual contaminants were still removable after decontamination. Persistent contamination highlights thus the necessity to optimize hair decontamination. To that end, head shaving is not recommended since it might lead to contamination spreading and to scalp skin lesions that would enhance dermal penetration of toxicants. Indeed, hair is able to trap contaminants, but their fate in hair is not well documented. More works are thus necessary to determine whether contaminants in hair could threaten the health of the contaminated person and be transferable.
