Abstract—In order to enable IoT nodes to efficiently use their energy harvesting capabilities, algorithms are used to determine a reasonable energy budget and allocate it to the node tasks, enabling energy neutral operation. However, most of these algorithms have been implemented and evaluated in simulation frameworks. In this paper, we evaluate the implementation of these algorithms to manage the energy of real-world LoRaWAN IoT nodes. We measure and compare the performance of the different energy budget estimation methods on a commercial LoRaWAN IoT platform. Results show that in this use-case, the choice of algorithm impacts the system Quality of Service by less than 15 %. This enables much simpler energy budget estimation methods to be used.

I. INTRODUCTION

Wireless sensor networking has recently been an active research area for both industries and academic institutions. In particular, a lot of work is focused on increasing the battery life of wireless sensor nodes. This can be achieved by reducing the power consumption of individual components power consumption, using duty-cycling strategies [1], or using low power transmission technologies such as LoRa. Yet the use of non-rechargeable batteries limits the lifetime of the system and creates waste when this battery is depleted. Thus, the use of energy harvesting and rechargeable batteries has been considered [2]. In such a system, more energy is made available to the node, enabling a longer lifetime of the system.

By adapting the Quality of Service (QoS) of the node to its energy harvesting capabilities, it is possible to reach an energy neutral operation point, and have a theoretically infinite battery life [3]. To do so, energy harvesting nodes use a power manager subsystem. This subsystem can be divided in two elements : an Energy Budget Estimator (EBE) which calculates an energy budget based on the harvested energy and the state of charge of the battery, and an Energy Allocator that decides how to spend this energy budget on different tasks, such as sensing, transmitting a message or processing data. Instinctively, we can see that the node QoS is linked to its EBE : a larger energy budget will enable a higher QoS, but will deplete the battery more quickly.

EBE algorithms can be model-based [4] [5], in which case they use the behavior of the energy source to adapt the energy budget according to an estimation of the future harvested energy. On the contrary, model-free EBE can be used independently of the used energy harvesting source. LQ-tracker [6], Fuzzyman [7] and RLMan [8] are examples of such algorithms, which respectively rely on linear quadratic regression, fuzzy logic and reinforcement learning to calculate an optimal energy budget. The performance of these algorithms has been verified and studied with extensive simulations.

However, to our knowledge, none of these algorithms have been implemented on commercial wireless sensor platforms. Moreover, these designs target short range communications, and the use of energy harvesting for Long Range IoT nodes has not been studied. In this paper, we compare the performance of four different model-free EBE algorithms in the context of a commercial implementation of solar powered LoRaWAN sensor nodes.

The rest of the paper is organized as follows. Section II describes the energy harvesting node platform and our design choices for the power manager. Section III details the implementation and choice of EBE algorithms. Section IV explores the tuning requirements of each algorithm. Section V shows and analyses our experimental results. Finally, Section VI concludes this article.

II. EVALUATION PLATFORM AND REQUIREMENTS

Our evaluation platform targets long range applications with multi-source energy harvesting capabilities [9]. Fig. 1 shows both hardware and software descriptions of the platform. An IoT node is usually composed of a micro-controller, a radio transceiver and some sensors, respectively a STM32L0, a SX1272 LoRa transceiver, and a connector to plug different sensors in our platform. Moreover, three SPV1050 energy harvesters enable simultaneous energy harvesting from a solar panel, a wind turbine and a thermo-electric generator. The harvesters use a common energy storage device which powers the platform through a DC to DC converter. The storage device can be a super-capacitor or a lithium-polymer (LiPo) battery.

Fig. 1: Evaluation platform overview.

In this work, a 7.5 F super-capacitor is used. Due to the board configuration, it is used between 3.7 V and 4.1 V.

The LoRaWAN technology uses the LoRa chirp spread spectrum (CSS) modulation to send short messages over long distances with a limited power consumption. LoRaWAN uses a star topology, where all the nodes send their messages to a gateway over unlicensed frequency bands. These bands are regulated to avoid interferences between radio devices. In Europe, LoRaWAN transmitters must respect a maximum duty cycle (i.e. 1% in the 868-868.6MHz sub-band and 0.1% in the 868.7-869.2 sub-band), which limits the maximal QoS of a LoRa node. The duration of a LoRa transmission depends on the payload size and the CSS spreading factor, which is - in short - the duration of a chirp and is dynamically modified according to the transmission conditions. A higher spreading factor enables a better sensitivity, increasing the transmission range, but reduces the throughput, increasing the energy cost of a transmission.

As we use a different radio technology, the operating conditions of the EBE algorithms differ from the state-of-the-art. The delay between two messages in our application ranges from minutes to hours, while the delay targeted by state-of-the-art EBEs ranges from seconds to minutes. This means that EBE algorithms will need more time to converge to the best result. Moreover, the energy consumption of a LoRa transmission is higher than lower range technologies due to long packet transmissions, which creates higher variations in the battery state-of-charge.

Usually, EBE algorithms are periodically executed, at the end of a timeslot (e.g. 1 hour), and aim to reach the energy neutral operation point for the next timeslot. In our application, to avoid a long convergence time, the EBE algorithm is executed after each transmission. The delay $D[k]$ to the next

message is calculated based on the current energy harvesting conditions. This enables greater agility, as the EBE can recover from a previous bad estimation more quickly. However, this also increases the variance of the QoS, as the algorithm has more difficulty converging to an optimized result.

III. EBE IMPLEMENTATIONS

The EBE algorithms have been implemented in a C library. Since the micro-controller has no Floating-Point Unit, the library was implemented using a portable fixed-point arithmetics library. This enables the validation of the EBE library on a computer before being implemented on a target node and speeds up development time.

Most EBE algorithms calculate an energy budget E_B for the starting timeslot based on the residual energy E_R of the energy storage device when E_B is calculated [6]. Some EBE algorithms [7] also need the measurement of the harvested energy E_H . However, the latter is difficult to perform with a good precision and low energy consumption overhead, and can sometimes be estimated by the residual energy variation ΔE_R . Some algorithms [8] are tightly coupled with the energy allocator and require typical energy consumption E_{Ctyp} .

Additionally, we define two applications parameters D_{max} and D_{min} , respectively as the maximum and minimum delay in seconds between two transmissions, used to set a minimal QoS. The library uses these parameters to calculate a minimal and maximal energy budget E_{Bmin} and E_{Bmax} . We also define D_{REF} as the delay between two transmissions when E_B is equal to E_{Ctyp} , set between D_{min} and D_{max} . These parameters are dependent on the end-application and are customizable. D (in seconds) is calculated from E_B and E_{Ctyp} as :

$$D = \frac{D_{REF} \times E_{Ctyp}}{E_B} \quad (1)$$

The library also needs information about the underlying hardware energy capabilities. We denote V_{BATT} , V_{min} and V_{max} the current, minimal and maximal battery voltage. V_{min} is the voltage for which the platform stops functioning, or can be set with a margin before the battery is fully depleted. When the energy storage is a super-capacitor, its capacitance C is defined. Based on these parameters, the current, minimal and maximal residual energy in storage E_R , E_{Rmin} and E_{Rmax} are calculated.

The evaluation platform is able to use multiple energy sources simultaneously. Model-based EBE are developed for a single source type, and are unsuitable for this use-case. Thus, model-free EBE algorithms are used. The resulting platform is more generic, and can be used in more end-user applications. In particular, we studied LQ-tracker [6] and Fuzzyman [7], which both showed good results in previous evaluation. LQ-tracker can be implemented using only the energy state-of-charge as input. While Fuzzyman in its original design also requires E_H , which is not measured in our platform. In this work, we consequently use a custom rule-set that uses ΔE_R as input instead of E_H , and uses the last energy budget $E_B[k-1]$ to determine the new E_B . The rules are detailed in Table 1 and only depends on the application and platform parameters and can be reused for a variety of applications and energy sources.

		E_R	
		Empty	Full
ΔE_R	< 0	E_{Bmin}	$f(E_B[k-1])$
	$= 0$	$f(E_B[k-1])$	$E_B[k-1]$
	> 0	$E_B[k-1]$	E_{Bmax}

TABLE I: Fuzzyman custom rule-set.

In Table 1 $f(E_B[k-1])$ is a function defined by :

$$f(E_B[k-1]) = \max \left(E_{Bmin}, \frac{E_R - E_{Rmin}}{E_{Rmax} - E_{Rmin}} \cdot E_B[k-1] \right) \quad (2)$$

Besides, we implemented two naive EBE algorithms : Linear_T and Linear_E. Linear_E calculates an energy budget between E_{Bmin} and E_{Bmax} as a prorata of V_{BATT} between V_{min} and V_{max} :

$$E_B = E_{Bmin} + (E_{Bmax} - E_{Bmin}) \times \left(\frac{V_{BATT} - V_{min}}{V_{max} - V_{min}} \right) \quad (3)$$

Linear_T calculates a fixed delay between D_{min} and D_{max} as a proportion of $V_{BATT}[k]$ between V_{min} and V_{max} . This delay is then converted to an energy budget based on E_{Ctyp} . The full equation is given by :

$$E_B = D_{REF} \times \frac{E_{Ctyp}}{D_{max} - (D_{max} - D_{min}) \times \left(\frac{V_{BATT} - V_{min}}{V_{max} - V_{min}} \right)} \quad (4)$$

These two algorithms are used as a performance baseline to evaluate the advantages of more advanced control algorithms. Their advantage is their simplicity, as no settings are required beyond the common platform settings. Finally, to avoid sharp E_B variations due to temporary change in energy harvesting conditions, all algorithms outputs are smoothed by an adaptive filter with a parameter $\beta = 0.9$:

$$E_{Bfiltered}[k] = \beta \times E_B + (1 - \beta) \times E_{Bfiltered}[k-1] \quad (5)$$

IV. EBE ALGORITHMS TUNING

All the selected algorithms can be tuned in order to improve their performance. The library has been designed to be portable, which enables the algorithms to be tuned in a simulation framework using the same code and same results. Indeed, it is much longer to run a full measurement campaign to validate an algorithm tuning settings than to run a simulation. This is particularly true for algorithms which provide many settings, such as Fuzzyman.

Each EBE algorithm has its tuning capabilities. Linear_T and Linear_E only need the common platform parameters, V_{min} and V_{max} , which can be adjusted to increase the efficiency of the EBE. LQ-tracker requires more parameters : it takes as input an energy target level E_{TARGET} , a step-size μ and two parameter vectors Φ and Θ . E_{TARGET} value is dependent on the application. μ is set by default to 0.001 and impacts how quick LQ-tracker converges. Fuzzyman is the hardest one to tune, as it can be entirely redesigned to fit the application. Indeed, it requires four thresholds THR_{Empty} , THR_{Full} , $THR_{Positive}$ and $THR_{Negative}$ to set the limits of the fuzzy inputs. Moreover, the entire rule-set may be redesigned to provide better performances.

For our simulation, the delay between two messages is set between of 15 minutes to 3 hours. The energy consumed by a LoRaWAN transmission is estimated to 140mJ with a SF7 spreading factor. We set V_{min} and V_{max} respectively to 3.7 V and 4.1 V, as for our real energy storage. The system was tested with a solar energy source, using EnHANTS [10] measurement data. The simulated solar panel measures 3.2 cm per 4.2 cm with an efficiency of $\phi = 10\%$, like the one used in experimentation. The simulation results, without tuning, are shown in Table II. The mean value $\bar{x}$ and standard deviation σ of V_{BATT} , E_B and D are presented.

We can first notice that all algorithms have some failed transmission, meaning some transmissions were aborted due to V_{BATT} being lower than V_{min} . Most of them occur around a lack of data in the solar traces, which we kept to simulate a long period without energy. Two algorithms, Fuzzyman and Linear_T, are more conservative, which can be seen as they keep a higher and more stable V_{BATT} , and thus emit less messages than the other two. E_B of Fuzzyman is high and unstable, which shows that it sometimes tries to deliver an E_B too high and can not stabilize. Linear_E and LQ-tracker, on the other hand, take more risks, showing a lower mean V_{BATT} , and are rewarded with a higher number of transmissions.

	Fuzzyman		Linear E		Linear T		LQ-tracker	
	$\bar{x}$	σ	$\bar{x}$	σ	$\bar{x}$	σ	$\bar{x}$	σ
V_{BATT} (V)	4.060	0.058	4.010	0.103	4.056	0.070	3.988	0.107
E_B (J)	0.454	0.163	0.446	0.125	0.364	0.155	0.529	0.107
D (min)	29	36	24	23	33	27	21	28
Tx	18201		22624		16452		25814	
Failed Tx	7		31		13		31	

TABLE II: Simulation before algorithm tuning.

We tried to improve the performance of each algorithm by tuning their parameters in order to maximize the number of transmissions. For Linear_E and Linear_T, we set V_{min} to 3.75 instead of 3.7 V, and V_{max} to 3.85 V instead of 4.1 V. This enables both algorithms to be more conservative when the energy storage is nearly depleted and take more risks when it is sufficiently replenished. We increase the step-size μ of LQ-tracker to 0.005, and leave Φ and Θ to their default values, fixed in [6]. Fuzzyman was given a new ruleset, shown in Table III, while the fuzzification thresholds THR_{Empty} , THR_{Full} , $THR_{Positive}$ and $THR_{Negative}$ were respectively set to $1.03 \times E_{Rfail}$, $0.85 \times E_{Rmax}$, 0.35 and -0.5 . The simulation was run again with the new settings, and Table IV shows the results.

ΔE_R	E_R	
	Empty	Full
	E_{Bmin}	$0.95 \times E_{B[k-1]}$
	$0.95 \times E_{B[k-1]}$	$1.5 \times E_{B[k-1]}$
< 0		
$= 0$		
> 0	$1.5 \times E_{B[k-1]}$	E_{Bmax}

TABLE III: Fuzzyman new ruleset.

	Fuzzyman		Linear E		Linear T		LQ-tracker	
	$\bar{x}$	σ	$\bar{x}$	σ	$\bar{x}$	σ	$\bar{x}$	σ
V_{BATT} (V)	3.978	0.116	3.985	0.109	3.996	0.100	3.988	0.107
E_B (J)	0.530	0.100	0.528	0.107	0.526	0.117	0.528	0.107
D (min)	20	27	21	27	21	27	21	28
Tx	26217		25947		25284		25800	
Failed Tx	36		33		28		31	

TABLE IV: Simulation after algorithm tuning.

After optimization, there is little difference between the performance of the different EBE algorithms. In our use-case, the energy budget E_B is limited between a minimal value E_{Bmin} and a maximal value E_{Bmax} . Thus all EBE algorithms have a similar behavior in limit cases where energy storage is sufficiently charged or empty. As all algorithms are tuned to maximize throughput, they deliver $E_B = E_{Bmax}$ for an extended range of input values, as shown in Fig.2, which shows the evolution of E_B as a function of the state-of-charge.

This graph gives a quick insight of how the different algorithms behave at low and high states of charge. This is useful to choose the EBE algorithm, as it hints to which algorithm is more or less conservative. However, this visualization has its limits when applied to algorithms which use more data inputs than only V_{BATT} , such as Fuzzyman, since it doesn't show the other inputs. Since all algorithms try to maximize E_B , they take less precautions and are more likely to fail if the environment conditions are bad for an extended time period. In the evaluated algorithms, LQ-tracker seems to be the most

conservative, starting to reduce the delivered E_B when the state of charge goes under 70 %. The Linear algorithms and Fuzzyman are more aggressive, delivering maximum E_B when the state of charge is respectively over 35 % and 17 %.

V. REAL-WORLD EBE MEASUREMENTS

During our experiments, each hardware platform is powered by a solar panel which can provide up to 5 V and 40 mA from direct sunlight. The experiment was run for seven days in an office settings. Each algorithm ran on a different hardware platform. All sensors were located next to a north oriented window, and ran in parallel to reduce differences in ambient energy. After each transmission, the energy budget and delay to the next transmission are calculated and sent through an UART, along with V_{BATT} and a count of successful transmissions. This UART transmission is logged by a computer, parsed and analyzed to produce the graphs shown in Fig.3.

The number of successful transmissions is approximately the same for all algorithms, within a 15 % margin. Only one transmission failed during the fifth night for Fuzzyman. This shows the algorithms are quantitatively equivalent provided they are properly tuned, which confirm the results obtained through simulation. Qualitative differences can however be observed between the different EBE implementations.

As expected, LQ-tracker, by being more conservative, keeps its V_{BATT} higher than the other algorithm, which makes it more able to survive long periods without energy. On the contrary, Fuzzyman delivers a competitive number of transmissions but keeps its V_{BATT} much closer to the failure threshold, making it more sensible to lack of energy input, as seen with the failed transmission. As Fuzzyman is highly tunable, this could be optimized by a carefully designed ruleset, to provide characteristics closer to LQ-tracker.

Moreover, Fuzzyman and Linear_T show a high variance in the delivered E_B and delay D , which can be explained by the quick decrease of E_B when V_{BATT} goes under a certain threshold, defined by the tuning of the algorithm. This quick E_B decrease translates into a much longer delay D , and decreases the performances of the algorithm, despite the aggressive tuning. On the other hand, Linear_E and LQ-tracker reduce E_B more progressively, which translates to a lower mean D and improved performances. This behavior also depends on how D is calculated from E_B , and could be varied using a different energy allocation method.

Fig. 2: E_B as a function of the State-of-Charge.

Fig. 3: EBE algorithms comparison over seven days.

Finally, it can be observed that all algorithms show a sharp rise of E_B when the energy storage gets replenished. As all the evaluated algorithms are model-free, they have no means to predict an approximate future energy state of charge. In our use-case, this is typically the case in the morning : the calculated D is long at the end of the night, when the energy storage starts getting replenished. When this long delay D is elapsed, the storage has been charging for a long time, and the EBE can deliver a higher E_B . This effect would be less important with a model-based EBE algorithm, as it would predict that energy was going to be harvested.

VI. CONCLUSION

This paper presents a practical implementation of Energy Budget Estimator algorithms for LoRaWAN IoT nodes and their optimization. We show that the choice of network technology has an impact on EBE algorithms implementation and performance. The use of a simulator shows that in our use-case, there are few differences between the different algorithms, provided they are all properly tuned. This enables the use of simpler EBE algorithms, which can then be more easily integrated in mathematical framework to size energy storage and energy sources based on Quality-of-Service requirements. Future work will focus on the development of such a framework, and on the allocation of the energy budget, especially for multi-task contexts.
