ABSTRACT

Texture segmentation constitutes a task of utmost importance in statistical image processing. Focusing on the broad class of monofractal textures characterized by piecewise constancy of the statistics of their multiscale representations, recently shown to be versatile enough for real-world texture modeling, the present work renews this recurrent topic by proposing an original approach enrolling jointly scale-free and local variance descriptors into a convex, but non smooth, minimization strategy. The performance of the proposed joint approach is compared against disjoint strategies working independently on scale-free features and on local variance on synthetic piecewise monofractal textures. Performance are also compared for multiphase flow image characterization, a topic of crucial importance in geophysics as well as in industrial processes. Applied to large-size images (above two million pixels), the proposed approach is shown to significantly improve state-of-the-art techniques relying on scale-free local features [3], well-suited for multiphase flow imaging [10], i.e. homogeneous textures as encountered in art investigation [9] or medical imaging [10], i.e. $s_\Omega \equiv s_0$ and $h_\Omega \equiv h_0$. The common approach to estimate $s$ and $h$ naturally involves the use of (weighted) linear regression across scales as

$$\log_2 x^{(j)}_\Omega \simeq \log_2 s_\Omega + jh_\Omega$$

When homogeneous texture are analysed, the multiscale coefficients are first averaged across space and then linear regressions on those averages lead to accurate estimates of $h_0$ and $s_0$, notably using wavelet leaders [3]. However, when the objective consists in obtaining local estimates to capture changes in $h$ or $s$, other strategies need to be deployed. In [8], estimation relies on a two-step procedure (as often in texture segmentation) consisting in (i) estimating $h_{\text{REG}}$ by linear regression across scales from $x^{(j)}_\Omega$ and (ii) obtaining from $h_{\text{REG}}$ a piecewise constant estimate of $h$ denoted $\hat{h}_{\text{TV}}$ by means of total-variation denoising. In [8], we also proposed to combine both steps by incorporating the regression weight estimation into the optimization process leading to:

$$\minimize_{h, w} \sum_{\Omega \in \Omega} \left( \sum_j \log_2 x^{(j)}_\Omega \right)^2 + \lambda \Omega(h, w)$$

where $\lambda > 0$ denotes a regularization parameter and $\Omega$ a convex regularization term inducing flexibility in the choice of the weights.
2. SEGMENTATION AS AN OPTIMIZATION PROCEDURE

We adopt a variational approach to estimate jointly \( s \) and \( h \) from the multiresolution quantity \( X \):

\[
\text{minimize } F(s, h; X) + G(s, h),
\]

where \( F(v, h; X) : \mathbb{R}^{[1]} \times \mathbb{R}^{[1]} \rightarrow \mathbb{R} \) is a data-fidelity term reminiscent of (2) and \( G(v, h; X) : \mathbb{R}^{[1]} \times \mathbb{R}^{[1]} \rightarrow \mathbb{R} \) is a penalization favoring piecewise constant estimates, based on the use of total variation. From (2), a natural choice for the data-fidelity term \( F \) reads:

\[
F(s, h; X) = \frac{1}{2} \sum_{j=1}^{J_2} \| \log_2 \chi^{(j)} - \log_2 s - jh \|_2^2,
\]

where \( 1 \leq J_1 < J_2 \). To manipulate convex data-term, we set \( v = \log_2 s \) and deal with the minimization problem over \((v, h)\) rather than over \((s, h)\) leading to

\[
(\hat{v}, \hat{h}) = \mathop{\text{Argmin}}_{v, h} \sum_j \| \log_2 \chi^{(j)} - v - jh \|_2^2 + \eta \text{TV}(h) + \zeta \text{TV}(v)
\]

with \( \hat{s} = 2^{\hat{v}} \), and where \( \eta > 0, \zeta > 0 \) are regularization parameters. TV models the isotropic total variation. Let \( D : \mathbb{R}^{[1]} \rightarrow \mathbb{R}^{[1] \times 2} \) computing the horizontal and vertical variations of intensity at each location \( n = (n_1, n_2) \in \Omega \),

\[
(D_y)_{n_1,n_2} = \left( \frac{y_{n_1+1,n_2} - y_{n_1,n_2}}{y_{n_1,n_2+1} - y_{n_1,n_2}} \right),
\]

the total variation is defined as, for every \( y \in \mathbb{R}^{[1]} \), \( \text{TV}(y) = \| \|Dy\|_2 \|_2 \) where for every \( z = (z_1, z_2) \in \mathbb{R}^{[1] \times 2} \),

\[
\|z\|_2 = \sum_{n_1=1}^{N_1-1} \sum_{n_2=1}^{N_2-1} \sqrt{\left( z_1 \right)_{n_1,n_2}^2 + \left( z_2 \right)_{n_1,n_2}^2}.
\]

3. STRONG CONVEXITY AND FAST ALGORITHM

3.1. Primal-dual algorithms and strong convexity

Problem (5) can be rewritten in a general form

\[
\hat{y} = \mathop{\text{Argmin}}_{y \in \mathcal{H}} \varphi(y) + \psi(Ly)
\]

where \( \varphi : \mathcal{H} \rightarrow \mathbb{R} \) and \( \psi : \mathcal{G} \rightarrow \mathbb{R} \) are proper lower semi-continuous convex functions defined on Hilbert spaces \( \mathcal{H} \) and \( \mathcal{G} \), and \( L : \mathcal{H} \rightarrow \mathcal{G} \) is a bounded linear operator. When the proximal operators of functions \( \varphi \) and \( \psi \), defined as \( \text{prox}_{\varphi}(y) = \mathop{\text{argmin}}_{\hat{y}} \frac{1}{2} \| y - \hat{y} \|^2 + \varphi(\hat{y}) \) (and similarly for \( \psi \)), have closed form expressions, this problem can be solved using Chambolle-Pock primal-dual algorithm [11], belonging to the class of proximal algorithms [12, 13] and particularly efficient when dealing with TV penalties.

When \( \varphi \) is \( \mu \)-strongly convex, it is proven in [11] that it is possible to design an accelerated algorithm, relying on adaptive stepsizes, to solve (8). This algorithm is detailed in Algorithm 1 where the sequence \((y[k])_{k \in \mathbb{N}}\) converges to the solution of (8).

**Algorithm 1: Accelerated Chambolle-Pock algorithm.**

Initialization : Set \( y^{[0]} = z^{[0]} = L y^{[0]} \)

Set \( \delta_0 > 0 \) and \( \nu_0 > 0 \) such that \( \delta_0 \nu_0 \|L\|^2 < 1 \).

for \( k \in \mathbb{N}^* \) do

\[
\begin{aligned}
&y^{[k+1]} = \mathop{\text{prox}}_{\delta_k \varphi} \left( y^{[k]} - \delta_k L^* z^{[k]} \right) \\
&z^{[k+1]} = \mathop{\text{prox}}_{\nu_k \psi} \left( z^{[k]} + \nu_k L y^{[k+1]} \right) \\
&\theta_k = (1 + 2\delta_k)^{-1/2}, \delta_{k+1} = \theta_k \delta_k, \nu_{k+1} = \nu_k / \delta_k \\
&z^{[k+1]} = z^{[k+1]} + \theta_k \left( z^{[k]} - z^{[k-1]} \right)
\end{aligned}
\]

end do

3.2. Strong convexity of the data-fidelity term

A differentiable function \( \varphi \) is \( \mu \)-strongly convex if and only if

\[
\langle \nabla \varphi(y) - \nabla \varphi(z), y - z \rangle \geq \mu \|y - z\|^2
\]

where \( \langle \cdot, \cdot \rangle \) denotes the usual scalar product. For the data-fidelity term considered here that is, \( \mathcal{H} = \mathbb{R}^{[1]} \times \mathbb{R}^{[1]} \) and \( \forall y = (v, h) \in \mathcal{H} \),

\[
\varphi(y) = \tilde{F}(v, h; X) = \sum_{j=1}^{J_2} \| \log_2 \chi^{(j)} - v - jh \|_2^2
\]

one directly finds \( \nabla \tilde{F}(v, h; X) = M (v, h)^T \), with \( M = \begin{pmatrix} S_1 & S_2 \\ S_1^T & S_2^T \end{pmatrix} \) is block matrix defined from

\[
S_m = \sum_{j=1}^{J_2} j^m,
\]

and \( I \) is the identity matrix of \( \mathbb{R}^{[1]} \). Since the gradient \( \nabla \tilde{F} \) is linear, the condition for \( \tilde{F} \) to be \( \mu \)-strongly convex rewrites: \( \forall (v, h) \in \mathcal{H}, \|
abla \tilde{F}(v, h; X), (v, h) \| \geq \mu \| (v, h) \|^2 \)

Moreover \( M \) is symmetric and positive definite, thus, denoting by \( \beta \) its lowest eigenvalue, \( \beta > 0 \) and

\[
\mu \geq \beta \left\| (v, h)^T \right\|^2
\]

we conclude that the function \( \tilde{F}(v, h; X) \) is \( \mu \)-strongly convex w.r.t the variables \( (v, h) \), with \( \mu = \beta \).
4. PERFORMANCE ASSESSMENT

Simulation settings – To evaluate the performance of the proposed piecewise constant local variance and local regularity estimation PLOVER procedure (cf. Algorithm 2), we generate piecewise monofractal textures fully characterized by their (piecewise) local variance $\tilde{\nu}$ and (piecewise) local regularity $\tilde{h}$. An example is displayed in Fig. 2(a), while underlying masks for local variance and local regularity are represented on Figs. 2(b) and (c). Synthetic textures consist of three regions embedded in a background, characterized with $\tilde{\nu}_n \equiv 0.3$ and $\tilde{h}_n \equiv 0.1$: Region 1 (left) corresponds to a change in local regularity $\tilde{h}$ (w.r.t. the background) but no change in local variance $\tilde{\nu}$; Region 2 (middle) corresponds to changes in both local variance and regularity ($\tilde{\nu}_n \equiv 0.6$, $\tilde{h}_n \equiv 0.6$); Region 3 (right) corresponds to changes in local variance only ($\tilde{\nu}_n \equiv 0.6$, $\tilde{h}_n \equiv 0.1$). The masks consisting of three different size disks permit to test the impact of region sizes on performance. Wavelet leaders, local suprema of wavelet coefficients [3] are chosen as multiresolution quantities $X$. Scales involved in the minimization range from $J_1 = 1$ to $J_2 = 5$.

Performance evaluation – Fig. 1 reports estimation performance compared i) when performing linear regressions equivalent to solve Problem (5) when $\eta = \zeta = 0$ leading to $(\tilde{\nu}_{\text{reg}}, \tilde{h}_{\text{reg}})$ and with $\tilde{\nu}_{\text{reg}} = 2^{\nu_{\text{reg}}}$ (column 1); ii) when applying a simple TV denoising on $\tilde{\nu}_{\text{reg}}$ and $\tilde{h}_{\text{reg}}$ separately, i.e., solving the minimization problem $\tilde{y}_{\text{TV}} = \text{argmin}_y \frac{1}{2} \| y - \tilde{y}_{\text{reg}} \|_2^2 + \lambda_y \| \nabla y \|_1 (\text{where } y = (s, h))$ (column 2); iii) when applying the proposed PLOVER procedure (column 3).

Fig. 1: Estimates for local variance (top) and regularity (bottom) : linear regressions (column 1), disjoint TV estimation (column 2), PLOVER (column 3). Average re-estimates for disjoint TV and PLOVER (columns 4 and 5 resp.)

3.3. Proposed algorithm for texture segmentation

Given the strong convexity result of the previous section, it is thus possible to use the general accelerated primal-dual Algorithm 1 for solving Problem (5). The iterations are customized to the minimization of (5) in Algorithm 2 setting $u = (\nu, h)$. The proximity operator of the data-fidelity term is provided in Proposition 1 while the proximal operator of the conjugate function of the mixed 2,1-norm is derived in [14]. The convergence of $(\nu^k, h^k)$ to a minimizer of Problem (5) is insured by $\delta_{\nu} \| D \|_2^2 < 1$.

Algorithm 2: PLOVER (Piecewise constant Local Variance and local Regularity joint estimation)

\begin{itemize}
  \item Initialization $\nu^{[0]}, h^{[0]} \in \mathbb{R}^{[1]}$, $u^{[0]} = \tilde{u}^{[0]} = D \nu^{[0]}$, $\ell^{[0]} = \ell^{[0]} = D h^{[0]} \in \mathbb{R}^{[1]} \times 2$; $\delta_{\nu}, \nu_{\text{th}} > 0$, s.t.
  \item for $k \in \mathbb{N}^*$ do
  \item \begin{align*}
    (\nu^{[k+1]}, h^{[k+1]}) &= \text{prox}_{\delta_{\nu} \frac{1}{2} \ell^{[k]}} \left( (\nu^{[k]}, h^{[k]}) - \delta_{\nu} \left( D \nu^{[k]} - \ell^{[k]} \right) \right) \\
    (u^{[k+1]}, h^{[k+1]}) &= \text{prox}_{\nu_{\text{th}} \| \cdot \|_2} \left( (u^{[k]}, h^{[k+1]}) + \nu_{\text{th}} D h^{[k+1]} \right) \\
    \ell^{[k+1]} &= \text{prox}_{\lambda \| \cdot \|_1} \left( \ell^{[k]} + \lambda \nu_{\text{th}} D h^{[k+1]} \right) \\
    \nu &\left( (1 + 2 \mu \delta_{\nu})^{-1/2}, \delta_{\nu} + \nu_{\text{th}} \right) = \frac{\nu_{\text{th}} \nu}{\nu_{\text{th}} + \nu_{\text{th}}} \\
    (u^{[k+1]}, h^{[k+1]}) &= \text{prox}_{\nu_{\text{th}} \| \cdot \|_2} \left( (u^{[k]}, h^{[k+1]}) + \frac{\nu_{\text{th}}}{\nu} \ell^{[k+1]} \right)
  \end{align*}
\end{itemize}

Proposition 1 (Computation of $\text{prox}\_\nu$). Let $\tilde{F}$ be defined as in (9). Let $S = \sum_j \log_2 X^{(j)}$, $T = \sum_j \{ j \log_2 X^{(j)} \}$ and $N = (1 + S_1)(1 + S_2) - S_1 ^2$, $S_m \in (0, 1, 2)$ defined in (10). For every $(\nu, h) \in \mathbb{R}^{[1]} \times \mathbb{R}^{[1]}$, $(p, q) = \text{prox}_{\nu}(p, h)$ with

\begin{itemize}
  \item \begin{align*}
    p &= (1 + S_2)(S + v) - S_1 (T + h) / N ,
    q &= ((1 + S_2)(T + h) - S_1 (S + v)) / N .
  \end{align*}
\end{itemize}

Fig. 2: (a) Synthetic piecewise monofractal textures using piecewise local variance (b) and regularity (c).

Because it is now well known that TV-based estimation suffers from large biases [15] that precludes the recovery of exact values for $\nu$ and $h$ in the different regions. To overcome this difficulty, we first perform a K-means segmentation from the estimates $(\hat{s}, \hat{h})$ and re-estimate from the multiscale coefficients $X$ the values of local variance and regularity for the segmented regions by global averages within segmented regions. Achieved performance are displayed in the fourth and fifth columns. $\lambda$, $\eta$ and $\zeta$ are chosen as those leading to the best SNR on these re-estimates.
Local regularity and variance estimation is clearly improved by the proposed joint estimation PLOVER procedure, compared to disjoint estimation. This is significantly the case for the local regularity estimates, a significant outcome as local regularity is a notoriously difficult quantity to estimate. Moreover, edges of estimates are found to be more regular for the proposed PLOVER procedure, an outcome of practical importance for multiphase flow analysis, where bubble perimeter estimation if of critical importance. For piecewise monofractal textures, it has been shown that texture segmentation state-of-the-art methods such as those in [1, 2] do not yield satisfactory results (cf. [8, Fig.3]), the corresponding comparisons not reported here for space reasons further confirm such findings.

5. MULTIPHASE FLOW LARGE-SIZE IMAGE ANALYSIS

Data acquisition – Experiments of joint gas and liquid flow through a porous medium were performed in a quasi-2D vertical cell (Hele-Shaw cell of width 210 mm, height 410 mm and gap 2 mm). The porous medium is an open cell solid foam of NiCrFeAl alloy, with a typical pore diameter of 580 µm. Constant gas and liquid flow rates are injected at the bottom of the cell through nine injectors (air) and a homogeneous slit (water). Images of the multiphase flow are acquired by a high-resolution camera (Basler, 2048 × 2048 pixels) at 100 Hz [16]. The size of the images to analyze is 1677 × 1160. An example is provided in Fig. 3(a), showing that the gas phase (blue or yellow structures) is textured because of the solid porous medium. The liquid phase (in green) is also textured though at smaller scales (cf. Fig. 3(b)).

Discussion – Figs. 3(c)-(d) clearly show that the local variance \( \hat{s} \) and local regularity \( \hat{h} \) provide information different in nature: \( \hat{h} \) captures well all gas bubbles and it can be conjectured that the value of \( \hat{h} \) is linked to bubble thickness variations ; \( \hat{s} \) brings forward bubbles located in the foreground only (yellow structures in Fig. 3(b)), thus providing rich information on the bubble distribution in the cell gap. Comparisons with state-of-art – Fig. 3 (2nd row) compares segmentation outcomes of the proposed PLOVER procedure to those obtained from state-of-the-art texture segmentation methods: Fig. 3(e) illustrates the segmentation obtained with the oriented watershed transform of Arbelaez et al [2] and Fig. 3(f) shows the segmentation obtained following Yuan et al [1] method based on matrix factorization. The results of disjoint TV estimation procedure [8] are displayed on Fig. 3(g). For disjoint TV and PLOVER results, the segmentation is obtained by performing K-means over \( \hat{h} \) and \( \hat{s} \). The proposed method PLOVER yields better determination of individual objects (bubbles), this is critically the case for the smaller size bubbles, of great importance in a forthcoming quantification of phase contact surfaces, critical features in multiphase flow characterization. In addition, PLOVER produces an enhanced separation of the foreground and background bubble populations, which yield an improved description of multiphase flows. Further, some state-of-the-art approaches are so demanding computational and memory-resource wise, that they could not be applied to the large-size images directly while the current PLOVER implementation permits a fast analysis of such large-size images. Results were hence compared for cropped versions of actual images.

6. CONCLUSION

These computational efficiency of PLOVER combined to the significant improvements in multiphase flow large-size image analysis pave the way towards a systematic use in this application. Analyses on much larger simulated and real-world image datasets are under current investigations together with the automated tuning of the hyper-parameters \( \lambda, \eta \) and \( \zeta \).
