MICROABSTRACT

Weight variations during treatment are associated with poor prognosis for early breast cancer patients. The study of body composition during adjuvant treatment is the key to understanding this interaction. With a median follow up of 3 years post-chemotherapy, our results show a small weight gain, but highlights that initial fatness in postmenopausal breast cancer patients promotes longitudinal 3-years weight gain.

ABSTRACT

Purpose: Weight change during adjuvant treatment for early breast cancer is associated with poor prognosis. The long-term evolution of body composition during adjuvant treatment for breast cancer, particularly endocrine therapy, is not well known and new data on this topic is required. The present study assesses the evolution of weight and body composition among 33 postmenopausal breast cancer patients currently treated with endocrine therapy after standard adjuvant chemotherapy including Taxanes.

Patients and Methods: Dual-Energy X-ray Absorptiometry (DXA) was used to measure fat and lean body mass. Body water was assessed by multifrequency bioelectrical impedance analysis. The HAD questionnaire and the short version of the IPAQ were also administered.

Results: During endocrine therapy, 15.2% (n=5) of the population lost weight and 36.4% (n=12) gained weight. The overall average gain was 2.0kg $\pm$ 5.5 (p= 0.04). During this period, fat mass, lean body mass and body water increased. Factors linked to fat mass gain are excess fat mass ($\geq$ 36%) before treatment and weight loss during chemotherapy. In the overall period of adjuvant cancer treatment, 30% of the population gained more than 5% of their initial weight. The average gain was the same as during the endocrine therapy period (2.0kg $\pm$ 5.4; p=0.031) and was characterized by an increase in total lean body mass, mainly localized in the trunk region.

Conclusion: Endocrine therapy appears as a pivotal period in weight and body composition management. Overfat/obese patients and those who lose weight during chemotherapy are more subject to weight and fat mass gain during endocrine therapy.

INTRODUCTION

Excess weight is well known to be a risk factor in breast cancer ^{1,2} and at the time of diagnosis is considered as a poor prognosis factor, with higher risks of recurrence and mortality ^{3,4}. There is also substantial evidence that weight change during cancer treatment could be associated with poorer prognosis among women with early breast cancer, whether weight gain or weight loss ^{3,5}.

Mechanisms to explain the adverse effect of weight variation have not been clearly identified but two hypotheses have been proposed ⁶: (i) adipose tissue is a source of oestrogen production and becomes the main source of oestrogen after the menopause, so a higher circulating oestrogen level associated with abdominal obesity is observed ⁷, especially in oestrogen-dependent postmenopausal cancer ^{1,3,8} and (ii) adipose tissue induces metabolic disturbances in the insulin and adipokine pathways.

As fat mass gain is the first hypothesis explaining the pejorative impact of weight gain, the evaluation of body composition is more appropriate than weight assessment. Weight and body composition variations among postmenopausal breast cancer patients have mainly been studied during chemotherapy. Water retention is one of the side effects of modern chemotherapy, particularly Taxane-based chemotherapy, ^{9,10} and it is also thought that weight gain during chemotherapy results from greater water gain than fat mass gain (NCT01506466, under submission). These results could explain the absence of relationship between weight gain and poor prognosis shown by recent studies ^{11,12}.

While several studies found that a fairly small weight gain occurred during endocrine therapy ^{13–16}, a recent retrospective chart review ¹⁷ shows that postmenopausal breast cancer survivors do not necessarily gain weight after two years of endocrine therapy. But little information is available about the impact of subsequent adjuvant treatment, among which endocrine therapy, on long-term body composition. In a double-blind placebo-controlled study with 24 months follow-up, an increase in lean body mass was observed among patients on aromatase inhibitors (AI) compared to those not treated with AI ¹³. In the same way, a randomized trial showed that a switch from tamoxifen to Exemestane induced body composition modification in overweight or obese patients, with a decrease in fat mass and an increase in the fat-free mass/fat mass ratio in the group of patients receiving AI, compared to the continued tamoxifen group ^{18,19}. In another study, after at least 6 months of AI, the total abdominal adipose tissue increase was about 9,1% in all subjects whatever the weight variation, reflecting an increase in the volume of visceral abdominal tissue ²⁰. This study highlights the importance of studying body composition, because weight variations do not reflect body mass distribution.

Body composition variation seems to differ markedly according to the type of treatment (chemotherapy, hormonotherapy) and for patients treated with both we do not know the impact of previous variations in weight and body composition under chemotherapy on variation during hormonotherapy.

To the best of our knowledge, no longitudinal study of body composition has been conducted on a cohort of early breast cancer patients treated with adjuvant chemotherapy, radiotherapy and then endocrine therapy. The aim of this study was to characterize the evolution in weight and body composition of postmenopausal breast cancer patients treated with adjuvant endocrine therapy (for more than one year) after chemotherapy. Factors influencing to these parameters during endocrine treatment, will also been investigated.

PATIENTS AND METHODS

Study population

From July 2015 to November 2016, 33 patients were enrolled in the MetaCa2 trial (NCT02509871) (see **Figure 1**). This study was approved by competent authority and the local ethics committee. All participants signed informed consent. All of them had participated in the previous MetaCa trial (NCT01506466) which investigated the evolution of body composition and related factors 1 month (T1) and 6 months (T2) after chemotherapy treatment (results under submission). Patients were invited to participate in the Metaca2 study only if they were currently receiving endocrine therapy. All patients were postmenopausal, and patients with a cancer relapse or another cancer were excluded.

Study outcomes

Data obtained in the Metaca study (T0-T1-T2) for the patients participating in the Metaca2 study were used for the longitudinal comparison of weight, body composition, anxiety/depression and time spent sitting. All measurements in the Metaca2 study were performed during a follow-up visit after a median time of three years following initiation of endocrine therapy [1,8 ; 4,5] (T3; see **Figure 2** : study design). The parameters were assessed according to the same methods as in the MetaCa study (NCT01506466; under submission).

Body weight

Body weight was measured to the nearest 0.1 kg in underwear and without shoes. The National Cancer Institute (CTCAE v.4.0) defines weight variation as a gain or loss greater than 5% of initial weight.

Body composition

Dual-Energy X-ray Absorptiometry (DXA) (Hologic 94 Discovery QDR; Hologic Inc, Waltham, Massachusetts) was used to measure fat mass and lean body mass and their distribution. A multifrequency bioelectrical impedance analysis (Bodystat Quadscan 4000) was used to evaluate total body water. To assess central fat distribution, waist circumference was measured to the nearest 0.5 cm with a standard tape measure placed between the lowest rib and the iliac crest, in standing position. In the same way, hip circumference was measured using standard tape placed horizontally on the widest point on the hip.

Physical activity

The short version of the International Physical Activity Questionnaire (IPAQ) was completed to evaluate time spent sitting per day in minutes and physical activity expressed in metabolic equivalent (MET) × minutes per week ²¹.

Anxiety and depression

Two validated self-administered questionnaires were used to evaluate anxiety and depression (Hospital Anxiety and Depression scale - HADs). The interpretation of this scale is based on the score: 7 or less means non-case, between 8 and 10 corresponds to a doubtful case and more than 11 reflects a definite case ²².

Statistical analyses

SEM software was used to perform data-management and statistical calculations ²³. Patient characteristics were described using mean ± standard deviation or median and [range] in case of non-Gaussian distribution, for quantitative parameters. For categorical parameters, counts and frequencies were calculated by category. The evolution of measures over time was tested using two-way ANOVA. Statistical relationships between pairs of variables where one variable was categorical were studied using Student's t-test, ANOVA (or Mann-Whitney U-test, Kruskal-Wallis H-test in case of non-Gaussian distributions and/or heteroscedasticity). When both variables were quantitative, Pearson's correlation coefficients (or Spearman rank correlations, if distributions were non-Gaussian) were calculated. All tests were two-sided and the standard significance threshold, $p \leq 0.05$, was used. Univariate analysis was performed using ANOVA to determine the parameters associated with weight and body composition variations (fat mass, lean body mass, body water). The parameters tested as potentially correlated with these variations between T2-T3 were age at diagnosis, age of menopause, medical history (arterial hypertension, smoking, hypothyroidism, lifetime weight variation, ongoing treatments, change in endocrine treatment), pre-adjuvant treatment factors (fat mass percentage, waist and hip circumference, W/H ratio, android fat mass/gynoid fat mass ratio, lean body mass), variation of other parameters for each period of

treatment (variation in weight, fat mass, and time spent sitting). Concerning T0-T3 variations, the same parameters were tested and body water variations for the different periods in the study were added.

Multivariate analysis using MANOVA was then performed, comprising all the factors selected in the previous univariate analysis ($p \leq 0.05$).

We decided to divide our population into two groups according to the body fat ranges proposed by Gallagher and colleagues ²⁴, more precise than a classification by BMI, and taking into account the pre-chemotherapy fat mass value of patients from MetaCa study. (DXA, T0). We classified each patient in the normal fat mass subgroup (fat mass <36%) or the overfat/obese subgroup ($\geq 36\%$ fat mass), according to initial fat mass percentage and adjusting for the age.

RESULTS

Patient characteristics

Patient and treatment characteristics are summarized in **Table 1**. On the basis of the pre-adjuvant treatment fat mass percentage (T0), 48.4% of the population was classified as having normal fat mass, 36.4% (n=12) as overfat and 15.2% (n=5) as obese. At the T3 evaluation, the median duration of endocrine therapy was 3 years [1.8; 4.5]. The large majority of patients were currently treated with aromatase inhibitors (97%). Only six patients had switched to a new endocrine treatment for reasons of tolerance: 2 from Tamoxifen to aromatase inhibitor and the others from one aromatase inhibitor to another.

Weight variations

During endocrine therapy (Between T2 and T3)

On average across the sample, a significant weight gain occurred after initiation of adjuvant antihormonal therapy ($+2.0\text{kg} \pm 5.5$) ($p=0.04$), i.e. between T2 and T3. Among these patients, 15.2% (n=5) lost weight ($-4.4\text{kg} \pm 0.9$ i.e. $-7\% \pm 1.4$ of their body weight), and 36.4% (n=12) gained weight ($+8.3\text{kg} \pm 3.6$ i.e. $12.1\% \pm 7\%$). In relation to the pre-adjuvant cancer treatment fat mass percentage (T0), only the subgroup of overfat/obese patients underwent a significant weight change between T2 and T3 ($p < 10^{-7}$). In this subgroup, the average weight gain was $3.8\text{kg} (\pm 5.6)$ ($p=0.012$).

Univariate analyses showed that the weight gain between T2 and T3 depended on four factors: fat mass class ($p=0.014$), waist ($p=0.043$) and hip circumference ($p=0.016$) at T0,

and weight variation during chemotherapy ($p=0.0059$). In multivariate analysis on these parameters, two still had a significant impact on the variation of weight between T2-T3. Firstly, weight variation during chemotherapy period ($p=0.000059$) and secondly the initial fat mass class ($p=0.00052$).

For the overall period of treatment (between T0 and T3)

Over the full period of cancer treatment, from the pre-adjuvant cancer treatment (T0) to a median time of three years of endocrine therapy (T3), the average weight increase was about 2.0kg (± 5.4) [-5.7; 22.2] ($p=0.031$) corresponding to a gain of 2.9% (± 7.9) compared to weight at T0. Nine percent ($n=3$) of the population lost more than 5% of their pre-adjuvant treatment weight with an average loss of 5kg (± 0.6), i.e. 8.3% (± 1.7). Thirty percent ($n=10$) gained more than 5% of their initial weight with an average weight gain of 7.9kg (± 5.9), i.e. 11.6% (± 8.4), and 61% remained stable ($n=20$).

The longitudinal evolution of weight according to the pre-adjuvant treatment fat mass percentage is presented in **Figure 3**. Weight was not significantly impacted by the different periods of treatment from T0 to T3 (only a trend in the effect of time is observed $p=0.07$). The initial fat mass percentage was significantly related to the longitudinal evolution of weight ($p=0.033$). In relation to initial fat mass percentage, while normal fat mass patients showed relative weight stability, overfat/obese patients lost weight during the chemotherapy period and then gained weight up to T3.

Several factors are associated with weight gain in the overall period of study (T0-T3), i.e. from pre-adjuvant treatment to a median time of three years after initiation of endocrine therapy. It was affected by age of menopause ($p=0.033$), whereby women menopausal before the age of 52 gained more weight than those menopausal later. Weight gain greater than 5% between T2 and T3 ($p=0.0003$), increase in fat mass between T2 and T3 ($p=0.031$) and increase in body water between T2 and T3 ($p=0.034$) were also significantly linked to weight gain between T0 and T3. Of these four significant parameters identified in the univariate analyses, three still retained significance in multivariate analyses. In descending order of probability, we find weight variation between T2 and T3 ($p=0.0015$), fat mass variation between T2 and T3 ($p=0.026$), and age of menopause ($p=0.04$). These three factors explain 41% of weight variation across the period of study (T0-T3).

Body composition variations

Changes in fat mass, lean body mass and body water

Body composition changes are presented in **Table 2**. The variations during the period of endocrine therapy (T2-T3) are presented in **Figure 4**. For the overall population, a significant gain in total fat mass is observed ($1.8\text{kg} \pm 3.8$; $p=0.0073$) mainly localized in the abdominal region ($1.4\text{kg} \pm 2.2$; $p=0.00031$). A significant increase in both total and trunk lean body mass also occurred, corresponding to a gain in body water. No significant variations were observed in the subgroup of normal fat mass patients. Overfat/obese patients, for their part, saw an increase in their total and trunk fat mass of about $2.8\text{kg} (\pm 3.5)$ ($p=0.0054$) and $2.2\text{kg} (\pm 2)$ ($p=0.00067$) respectively. They also gained total ($1.4\text{kg} \pm 2.2$; $p=0.024$) and trunk (1.4 ± 1.6 ; $p=0.0048$) lean body mass, corresponding to a gain in body water ($1.4\text{kg} \pm 1.6$; $p=0.0052$) at intracellular level (1.5 ± 2.6 ; $p=0.047$).

Fat mass gain between T2 and T3 was linked to the initial fat mass class ($p=0.053$), weight variation between T0 and T1 ($p=0.00031$) and time spent sitting (T1-T2) ($p=0.05$). All these parameters were still significant in multivariate analyses. These factors explain 44% of fat mass variation between T2 and T3, i.e. from six month post-chemotherapy to a median time of three years post initiation of endocrine therapy. Concerning body water variation between T2 and T3, when the parameters identified as significant in the univariate analyses (i.e. pre-adjuvant treatment fat mass class and weight variation between T0-T1) were tested in multivariate analyses, we did not find any variable implicated in the variation.

Over the whole period of treatment (T0-T3), body composition in the overall population ($n=33$) is characterized by a significant increase in total lean body mass ($+1.5 \pm 3.2$; $p=0.0083$) especially in the trunk region ($+0.85\text{kg} \pm 2$; $p=0.015$). These variations reflect the variation occurring in the subgroup of overfat/obese patients where a gain in total lean body mass ($2.1\text{kg} \pm 3.7$; $p=0.034$) and trunk lean body mass ($1.3\text{kg} \pm 2.3$; $p=0.034$) was observed. No variation in fat mass was observed in the overall population nor in the subgroups of patients.

Lean body mass variation between T0 and T3 was linked to age of menopause ($p=0.0084$), initial fat mass percentage ($p=0.043$), weight variation between T2-T3 ($p=0.02$), fat mass variation between T0-T1 ($p=0.035$) and body water variation between T2-T3 ($p=0.000076$). Multivariate analyses revealed that four factors were significantly associated with lean body mass variation between T0-T3: weight variation between T2-T3 ($p=0.0009$), age of menopause ($p=0.0026$), body water variation between T2-T3 ($p=0.0067$) and finally fat mass variation during the chemotherapy period (T0-T1) ($p=0.03$). More than half of the lean body mass variation between T0 and T3 is explained by these factors (57%).

Changes in waist and hip circumference

During the T2-T3 period, there was no significant difference in the waist to hip ratio (W/H ratio) ($p=0.55$), whether in the overall population or in the different subgroups. Nevertheless, during this period, significant increases in both waist and hip circumferences are observed for overfat/obese patients, respectively $+7.5\text{cm} \pm 7.5$ ($p=0.0017$) and $+4.8 \pm 4.6$ ($p=0.0012$).

Overall, no significant change was observed in the evolution of the W/H ratio. Nevertheless, the subgroup of overfat/obese patients had a W/H ratio of over 0.85, meaning android obesity, throughout the study (from T0 to T3). In the same way, from the beginning of the study to the last follow-up, their waist circumference was over 90 cm, also characterising android obesity. Their waist circumference increased about 8.5cm (± 7.8) ($p=0.0013$) between T0 and T3.

Analysis of results on the short version of the IPAQ questionnaire

Overall, time spent sitting increased by about 112 minutes (± 154) on average from pre-adjuvant treatment (T0) to a median time of three years post initiation of endocrine therapy (T3) ($p=0.00048$). More precisely, between T2 (six month post chemotherapy) and T3, an increase of about 100.4 minutes (± 166) ($p=0.0042$) was observed. Regarding subgroups, only overfat/obese patients exhibited significant variations in their time spent sitting in these two periods, i.e. T0-T3 and T2-T3. Nevertheless, in our population at T3 evaluation, 91% ($n=30$) of the patients reported more than 750 MET.min/week and only 6% reported less than 450 MET.min/week ($n=2$).

Analysis of the HAD questionnaire

In the overall population, at T3, we found that 21.2% ($n=7$) of the patients had an anxiety score between 8 and 10 and 33.3% ($n=11$) had a score over 11 revealing a state of anxiety. Concerning the depression score, 85% ($n=28$) of the population had a score under the threshold and 6% ($n=2$) had a score reflecting depressive symptoms. However no significant changes in anxiety and depression levels were observed over the period of treatment.

DISCUSSION

This trial assessed the body composition evolution among postmenopausal breast cancer patients after a median time of three years of endocrine therapy post-chemotherapy, and studied factors implicated in variations observed.

After a median follow-up of 3 years of endocrine therapy (T2-T3), we found a mean weight gain of about 2.0kg (± 5.5). This result is consistent with previous studies, which reported a weight gain under endocrine treatment of around 2kg. Baum and colleagues²⁵ studied

weight variations over 24 months in three groups of postmenopausal patients treated with either anastrozol alone, or tamoxifen or a combination of both, and observed a similar gain in the 3 groups with a mean of 1,65 kg over the 24 months of follow-up. Another study¹³ showed a gain of $1,76 \pm 0.66$ kg in postmenopausal women treated with aromatase inhibitor as well as in those who were not treated with aromatase inhibitor over 24 months. Heideman's team²⁶ evidenced a mean weight gain of $2,6 \pm 6$ kg in patients treated combined systemic treatment (chemotherapy + endocrine therapy) one year post diagnosis. We showed that weight loss during chemotherapy (T0-T1) and a high initial fat mass percentage were the strongest parameters associated with the weight gain during endocrine therapy. This is in accordance with a recent review, which highlights that weight gain in the first two years of endocrine therapy is associated with weight loss between diagnosis and the beginning of endocrine therapy¹⁷.

In our study, this weight gain during endocrine therapy corresponds to an increase in fat mass mainly located in the abdominal region and an increase in lean body mass mostly corresponding to body water. Concerning lean body mass, in the study by Battisti and al.,²⁰ patients treated with aromatase inhibitor showed an increase in lean body mass and in the lean body mass/fat mass ratio. Similar results were found in a double-blind, placebo-controlled randomized trial, with 24 months follow-up. Only a gain in lean body mass was observed, and no changes in body fat mass were reported in the group of patients treated with aromatase inhibitors compared to those who were not¹³. The authors explain that this lean body mass gain can be induced by the inhibition of aromatase, leading to an accumulation of androgens that are known to be linked to muscle protein synthesis. Nevertheless, both of these studies evaluated body composition only from DXA and did not perform bioelectrical impedance analysis, so that no conclusions were drawn on body water. Our study shows that the gain is mainly due to an increase in intracellular water retention. In addition, as previously described by Battisti and colleagues²⁰, variation in abdominal fat mass distribution is observed in women under aromatase inhibitor treatment, and particularly an increase in visceral adipose tissue (i.e. contained in the abdominal cavity). With a follow-up of around 4 years after initiation of endocrine therapy, the authors observed an increase in total abdominal adipose tissue of 9.1%, which is equal to the increase in total fat mass percentage observed in the present study after endocrine therapy initiation (T2-T3). Nevertheless, we found a greater increase than in this study (17.5%) over 36 months follow-up.

During endocrine therapy, weight loss during chemotherapy, initial fat mass class and increase in the time spent sitting after diagnosis are the main parameters associated with fat mass gain. It has been shown that treatments exacerbate the decrease in physical activity²⁷⁻

²⁹ and increase time spent sitting ³⁰. However, the literature reports that more than the half of the patients are insufficiently active at the time of diagnosis ^{29,31}. In our study, after a median time of three years post initiation of endocrine therapy (T3), we found that the majority of the population had a level of physical activity of over 750 MET.min/week. International recommendations for physical activity advise 150 minutes/week of moderate activity (3 to 6 MET/week) i.e. between 450 and 750 MET.min/week ³². These recommendations have been extended to breast cancer patients ^{33–35} and many studies have shown the benefits for patients of staying active during treatment, in particular in reducing the risk of death and relapse ³⁶. Furthermore, being active is of particular interest in reducing fat mass and improving muscle strength ^{37–39}. It is also important to underline that reducing sitting time is associated with a decrease in mortality ^{40–43}. More precisely, it has been shown that the replacement of one hour sitting by one hour standing per day significantly reduces mortality ⁴³. Currently, it is really important to establish physical activity programmes during treatment to encourage patients to comply with international recommendations, particularly in the subpopulation that we have identified. Indeed, as demonstrated in our study, patients with a high initial fat mass percentage are the most exposed to weight variation in the course of treatment, and especially to fat mass gain in the long term, which accumulates predominantly in the trunk region suggesting accumulation of visceral adipose tissue which is associated with cardio-metabolic complications ^{6,20,44}.

Several studies ^{26–28} have described a weight gain in the year following diagnosis, but none according to the sequence of treatment. On the over period of evaluation in this study (from the initiation of chemotherapy to the 3 years of endocrine treatment i.e. 3 years and 6 months of follow-up), we observed a weight gain of 2.0kg and this gain was principally due to the weight gain during endocrine therapy. In our study, we did not find any weight gain during the first 9 months after adjuvant treatment initiation in our MetaCa cohort (NCT01506466) (T0-T2: from initiation of chemotherapy to 6 months after the end). The weight gain occurred later i.e. during endocrine therapy, and corresponds to a fat mass gain. Endocrine therapy appears to be a pivotal period to explain weight change during endocrine therapy.

Several studies have highlighted that weight variations, either gains or losses, during chemotherapy are implicated in poorer prognosis ^{5,27,45,46}. The mechanisms of a pejorative impact of weight gain could be explained by the fat mass gain, but for weight loss, they are not clear. Our study shows fat mass gain consecutive to a weight loss during the chemotherapy period. We can hypothesise that losing weight during chemotherapy is associated with a gain in fat mass during endocrine therapy more particularly for patients with fat mass excess (overfat/obese). Previous weight loss could be linked to the later gain through fat overshooting as previously reported in energy restriction ⁴⁷. Remarkably, during

endocrine therapy, we observed a gain in fat mass particularly in the trunk region. Abdominal fat mass excess is well known to be associated with poor prognosis for breast cancer patients ^{48–50}. One of the mechanisms explaining this relationship is that visceral adipose tissue is associated with metabolic syndrome ²⁰ and with insulin resistance ^{6,44}. There is a need to conduct long-term studies on a larger population to explore this hypothesis.

CONCLUSION

The effects of adjuvant endocrine therapy on body composition among postmenopausal breast cancer survivors were studied in this trial. With three-year hindsight after endocrine therapy initiation, a fairly small weight gain is observed but it is associated with changes in body composition distribution. Indeed, patients gain in fat mass particularly in the trunk region. Overfat/obese patients and those who lost weight during chemotherapy were more subject to weight and fat mass gain during endocrine therapy.

CLINICAL PRACTICE POINTS

- While several studies have described weight and body composition variation during chemotherapy for early breast cancer, to the best of our knowledge, ours is the first longitudinal study conducted on a cohort of postmenopausal patients treated with chemotherapy, radiotherapy and endocrine therapy.
- Only a fairly small weight gain is observed with a follow-up of 3.6 years post chemotherapy, but it corresponds to the weight gain observed during the endocrine therapy period.
- Overfat/obese patients are more susceptible to a fat mass gain during endocrine therapy than normal fat mass patients. This highlights the interest of nutritional and physical activity interventions focusing also in reducing time spent sitting in this population at the beginning of treatment.
- Further longitudinal cohort studies are needed to confirm these results.

TABLES CAPTIONS

Table 1: Characteristics of patients

Abbreviations: BMI = body mass index; FEC = 5fluorouracile, epirubicin and cyclophosphamide

Table 2: Body composition variations

Weight variation was defined by a gain or loss greater than 5% of initial body weight. T0-T3 covers the entire period of the study, from pre-adjuvant treatment to a median follow up of 44 months including endocrine therapy. T2-T3 corresponds to a period of 34 months. Endocrine therapy was started on average 3 months before the T2 measurement point. *SD: standard deviation; Bold values correspond to $p < 0,05$.*

FIGURES CAPTIONS

Figure 1: Flow chart

Six patients from the previous study, MetaCa, are not currently treated with endocrine therapy and three had no DXA measures at T0 or T2, and/or they did not meet selection criteria. Of the forty-three potential inclusions, nine patients refused to participate in the study and one patient had a cardiac device that prevented the DXA measure, corresponding to a non-inclusion criterion.

Figure 2: Study design

All patients were included in the MétaCa2 trial on the occasion of a follow-up visit for their endocrine therapy treatment. All the measurements performed at T3 had already been performed at T0, T1 and T2 (MétaCa trial). *RTX: Radiotherapy; DEXA: Dual-energy Xray absorptiometry; IPAQ: International physical activity questionnaire; HAD: Hospital anxiety and depression scale*

Figure 3: Percentage of weight variation according to initial fat mass percentage groups

Overfat/Obese patients exhibited more weight changes across the different periods in the study than normal fat mass patients. The difference between the curves is significant ($p = 0.033$) but no time effect is evidenced ($p = 0.07$).

Figure 4: Body composition variations between T2 and T3

Only the subgroup of overweight/obese patients exhibited statistically significant variations in body composition in the trunk region compared to the healthy subgroup. *Statistically significant ($p < 0,05$). Mean $\pm$ SEM.

TABLES

Table 1

General characteristics		
Age at T3 (years), median		64 [55; 75]
Mean weight at T3 (kg)		70 $\pm$ 15
Mean BMI at T3 (kg/m ²), n (%)		26,9 $\pm$ 6,4
	BMI < 25	16 (49)
	25 $\leq$ BMI < 30	8 (30)
	BMI $\geq$ 30	9 (21)
Age at menopause (years), median [min; max]		51 [45; 59]
Initial fat mass percentage (T0), n (%)		
	Normal fat mass : < 36%	16 (48,5)
