Abstract

The ability of viscoplastic fluids to self-select their flow geometry through the formation of unyielded dead zones has important consequences for flows in wavy channels, flows over obstacles, etc. Yet, the mechanisms controlling the formation and dimensions of the dead zones remain poorly understood. We present a detailed cross-comparison of experimental and numerical results concerning channel flows of a viscoplastic fluid over a rectangular cavity filled by the same material. In all the configurations studied, which correspond to moderate values of the Bingham number, a continuous dead zone forms inside the cavity. Both numerical and experimental data reveal that, unlike at high Bingham numbers, the shear-rate profiles above the dead zone display an asymmetric shape. Accordingly, two different flow zones can be distin-

guished: a Poiseuille-like zone, in which the velocity profile is similar to that over a rigid wall, and a boundary layer ensuring the transition with the dead zone below. It is shown that the effective boundary condition felt by the Poiseuille-like layer is essentially controlled by incoming flow characteristics, such that the thickness of this layer does not obey simple relations with cavity length. Interestingly, however, the thickness of the boundary layer appears to follow a generalized Oldroyd’s scaling with cavity length.

1. Introduction

In this article, we study the flow of viscoplastic fluids in expansion – contraction confined domains. A striking feature of such configurations is the

20 self-selection of the flowing region through the formation of fully unyielded
dead zones and moving plugs [1]. Detailed numerical investigations have
shown that various topologies of unyielded zones can occur, depending on
incoming flow and channel characteristics [2, 3, 4]. However, understanding
the mechanisms that govern the location of the yield interfaces remains an
25 open issue. In real yield-stress fluids, further complexity can also be intro-
duced by additional rheological trends of the materials, such as viscoelasticity
or thixotropy, that may also play an influence on the formation of unyielded
zones [5, 6]. In this article, we want to shed light on the flow properties in the
vicinity of the yield interfaces, with the objective to exhibit possible generic
30 scaling relations. We consider more specifically the configuration of a lon-
gitudinal parallel flow over a rectangular cavity [7, 8] and, through detailed
cross-comparisons between numerical simulations and physical experiments,
focus on features induced by *genuine* viscoplasticity only.

Depending on whether numerical or experimental results are concerned,
we will consider the Bingham or the Herschel-Bulkley (HB) constitutive law
for the deviatoric stress tensor τ :

$$\left\{ \begin{array}{l} D(\mathbf{u}) \neq 0 \Leftrightarrow \left\{ \begin{array}{l} \tau = 2\eta D(\mathbf{u}) + \tau_y \frac{D(\mathbf{u})}{|D(\mathbf{u})|} \text{ (Bingham: simulations) or} \\ \tau = 2K |D(\mathbf{u})|^{n-1} D(\mathbf{u}) + \tau_y \frac{D(\mathbf{u})}{|D(\mathbf{u})|} \text{ (HB: experiments)} \end{array} \right. \\ D(\mathbf{u}) = 0 \Leftrightarrow |\tau| \leq \tau_y, \end{array} \right. \quad (1)$$

where τ_y is the yield stress (in Pa), η and K are respectively the Bingham
viscosity and HB consistency (resp. in Pa·s and Pa·s^{*n*}), n is a power-law
index, $\mathbf{u}$ is the velocity, and $D(\mathbf{u}) = (\nabla \mathbf{u} + \nabla \mathbf{u}^T)/2$ is the strain rate tensor.
We adopt the following convention for the tensor norms:

$$|T|^2 = \frac{1}{2} \sum_{i,j} T_{i,j}^2.$$

Clearly, Bingham law corresponds to a particular case of Herschel-Bulkley
law for $n = 1$ (and $K = \eta$). In the following, we assume that the Reynolds
number (Re) is low, so that the flows are only controlled either by the Bing-
ham B or by the Herschel-Bulkley number Hb , commonly referred to as
viscoplastic numbers, defined as:

$$B = \frac{\tau_y}{\eta} \frac{\mathcal{L}}{\mathcal{U}} \quad \text{and} \quad Hb = \frac{\tau_y}{K} \left(\frac{\mathcal{L}}{\mathcal{U}} \right)^n, \quad (2)$$

where $\mathcal{L}$ and $\mathcal{U}$ denote characteristic length and velocity scales, respectively. Note that various choices for the characteristic scales $\mathcal{L}$ and $\mathcal{U}$ will be considered in the following, leading to different definitions of the viscoplastic numbers B and Hb (specified by different subscripts).

Recently, compelling analytical predictions for the location of yield interfaces in viscoplastic flows over a cavity were obtained by Balmforth *et al.* [4] in the limit of high Bingham numbers. In this regime, these authors show that the sheared flow layer developing between the unyielded zones behaves as a *viscoplastic boundary layer*. The theory of viscoplastic boundary layers goes back to Oldroyd [9], who studied analytically different flow configurations including a jet intrusion of Bingham fluid in an infinite half-plane and a moving knife in an infinite plane. Oldroyd derived an asymptotic approximation of the momentum conservation equation for high Bingham numbers, and obtained similarity solutions for the velocity profile in the yielded zones, dubbed boundary layers. The width of these boundary layers evolves according to $B_\ell^{-1/3}\ell$, where ℓ denotes the abscissa and B_ℓ corresponds here to a local Bingham number defined on the basis of ℓ . This problem has then been studied in other configurations, *e.g.* the flow around an obstacle where an alternative scaling in $\mathcal{O}(B^{-1/2})$ was proposed [10], or in a Hele-Shaw cell [11]. Through asymptotic analysis and numerical simulations, Balmforth *et al.* [4] revisited Oldroyd’s viscoplastic boundary layer theory in various configurations and provided a rationalization of the apparently incompatible scalings previously proposed. In short, both scalings in $\mathcal{O}(B^{-1/3})$ and $\mathcal{O}(B^{-1/2})$ can occur, depending on whether the zone bounding the viscoplastic boundary layer is an unyielded layer or a wall. In the case of the flow over a cavity, they showed that the thickness of the boundary layer obeys Oldroyd’s scaling in $B_D^{-1/3}D$, where D denotes the length of the cavity. Noteworthy for the following is the fact that Balmforth *et al.*’s analysis assumes shear-rate profiles in the flow layer that are symmetrical with respect to the center of the layer.

In this paper, we investigate whether the results of [4] concerning the case of cavity flow can be extended to the case of *moderate* viscoplastic numbers, *i.e.* outside of the *a priori* domain of validity of the asymptotic approximation but for a range of parameters that is more relevant of applications. The work is based on a re-analysis of the experimental results described in [8] through comparisons with highly-resolved numerical simulations. Section 2 briefly recalls the experimental and numerical methods, which are described in full details in [8] and [3], respectively. In section 3, we highlight the

common features and trends observed in experiments and simulations, and show that the location of the yield interfaces cannot be predicted through Oldroyd's scaling in our case. Section 4 shows that a sub-layer of the shear zone does nevertheless behave as a viscoplastic boundary layer, and that the thickness of this layer indeed obeys a generalized Oldroyd's scaling in both simulations and experiments. Lastly, section 5 presents final remarks.

2. Methods

2.1. Experimental setup

Figure 1: (a) Experimental setup (bottom) and streamlines for an experiment with $D = 1.5 \text{ cm}$, $h = 3 \text{ cm}$, fluid F3 and flow rate $Q = 6.4 \text{ cm}^3/\text{s}$. The pattern of streamlines is visualized by computing the standard deviation of local pixel gray levels over a 1-minute image sequence (2723 images). (b) Numerical simulation for the same geometry and fluid, for $Q = 8 \text{ cm}^3/\text{s}$. The unyielded plug and dead zones are colored darker. We also sketch the location of the coordinate system, with $y = 0$, corresponding to cavity top.

The experimental setup was described in [8]. As shown in Figure 1(a), it consists of a closed rectangular channel with a height $H = 6.5 \text{ cm}$, a length of 30 cm, and a width of 8 cm. Two steps are placed in the cell to form a

central cavity of height h (equal to 1.5 or 3 cm). The cavity length D is equal to 1.5, 3 or 6 cm. In the following, the x axis corresponds to the longitudinal direction of the cell, while y denotes the cross-stream vertical direction. Note that y is oriented upwards, with $y = 0$ corresponding to the top of the cavity.

Stationary laminar flows are generated by connecting the cell to a pump imposing a constant flow rate Q . We use a transparent model yield-stress fluid, namely Carbopol micro-gel solutions, whose rheological behaviour is well described, in steady state, by a Herschel-Bulkley law [12, 13]. Note however that this material also features viscoelastic properties that can induce additional complexity to the flows [14, 7].

Using reflective tracers (hollow spheres) illuminated with a laser sheet, velocity fields $\mathbf{u}$ within the flow are reconstructed through particle image velocimetry (PIV). The local shear rate $D(\mathbf{u})$ is computed by direct differentiation of the velocity field, and stress fields are then derived by application of Herschel-Bulkley constitutive law. Figure 1(a) presents a visualization of the streamlines obtained in a typical experiment. Note that in the vicinity of the cavity center (denoted by $x = x_{1/2}$ in the following), the flow can be considered as quasi-longitudinal, *i.e.* vertical velocity components are negligible. We can therefore spatially average PIV measurements in this region, to obtain cross-section profiles of longitudinal velocity with a higher accuracy. For more details, we refer to [15, 8].

2.2. Numerical simulations

As already mentioned, we assume $Re \ll 1$ and neglect inertia terms. We thus solve numerically the following viscoplastic Stokes system (where p denotes a modified fluid pressure accounting for the hydrostatic contribution):

$$\begin{cases} \partial_x p = \partial_x \tau_{xx} + \partial_y \tau_{xy}, \\ \partial_y p = \partial_x \tau_{xy} + \partial_y \tau_{yy}, \\ \text{div}(\mathbf{u}) = 0. \end{cases} \quad (3)$$

A Bingham rheology is considered in the simulations. The computations are performed with a parallel 2D code (implemented with F90 and MUMPS (MPI)) based on Augmented Lagrangian methods. It shall be noted that fine meshes are used, together with demanding convergence criteria of the Augmented Lagrangian iterations, leading to very well defined and sharp localization of the yielded / unyielded material interfaces. As a consequence, strain rates and stresses are computed with high accuracy. For more details,

we refer to [3], where the code was validated and compared to the physical experiments of [16] and [15]. We recall that the simulated configuration is a full expansion-contraction, so that the flow conditions on the upper half of the domain are not exactly the same in the experiments (*plane* upper wall as shown in Fig. 1(a, down)) and in the simulations (*symmetric* cavity facing downwards; this full geometry is shown in [3]-Fig. 2)). It was checked that, in spite of this difference, the same bottom-half analytic viscoplastic Poiseuille profiles are recovered in both the entry and exit channels (see [3] for more details). It was also shown that the simulations are able to retrieve several non-trivial qualitative features of the experiments. In particular, as illustrated in Figure 1b, the overall simulated flow pattern in the bottom-half of the domain above the cavity indeed appears in good qualitative agreement with the experimental observations. Based on these first comparisons, we argue that the differences in rheological model and geometrical configuration between the simulations and the experiments shall not constitute an obstacle to the comparison of both data sets, at least as long as the focus remains on main trends and qualitative features.

2.3. Fluid rheological parameters and flow regimes

The Herschel-Bulkley rheological parameters of the five Carbopol samples used in the physical experiments are recalled in Table 1. Note that while the yield stress τ_y and consistency K of the different fluids vary, the exponent n remains close to 0.4 in all cases. As the numerical simulations are performed with a Bingham model, we adapted the rheological parameters considered in the computations to obtain comparable flow configurations. To do so, for a given experiment, we needed to adjust two parameters in the code, namely the Bingham viscosity η and the "driving pressure" term. These two parameters are fixed through the two following constraints: (i) the plug velocity (*i.e.* the maximum velocity) in the center of the channel is the same as in the experiment, and (ii) the viscosity η is computed from K and the estimated maximal strain rate in the middle of the cavity (at $x = x_{1/2}$) obtained in the experiment. The yield stress τ_y is taken identical to the experimental value. These adjustments guarantee that shear-rate values are on the same order in both simulations and experiments (within a factor of 3, typically), and that the two underlying constitutive laws are reasonably close to each other in the considered shear-rate range.

For the sake of clarity, Table 2 summarizes the different definitions of Bingham and Herschel-Bulkley viscoplastic numbers that will be used in the

Symbol	Fluid	τ_y (Pa)	K (Pa·s ⁿ)	n
☆	F1	0.2	1.1	0.45
△	F2	0.8	1.4	0.44

$D = 6$ cm, $h = 1.5$ cm
$D = 6$ cm, $h = 3$ cm

Figure 2: Colors legend used, in the following figures of the article, for the various geometries of the cavity.

following. The numbers B_{up} and Hb_{up} , defined on the basis of maximum flow velocity U_{up} at cavity entrance and upward channel width $(H - h)/2$, characterize the incoming viscoplastic flow upward of the cavity. The numbers B_D and Hb_D , defined on the basis of U_{up} and cavity length D , correspond to those involved in classical Oldroyd's scaling. Lastly, we will also introduce the numbers B_{cav} and Hb_{cav} based on an internal flow velocity above the cavity U_s and cavity length D (see section 4.2). The configurations investigated in this study correspond to *moderate* values of the upward viscoplastic numbers B_{up} and Hb_{up} : the range of Hb_{up} investigated in the experiments is 0.2–5, while the corresponding range of B_{up} in the simulations is 0.5–40.

Table 2: Characteristic length and velocity scales $\mathcal{L}$ and $\mathcal{U}$ (see Eq. (2)) used to define the different Bingham and Herschel-Bulkley viscoplastic numbers introduced in this study.

Simul./Exp.	$\mathcal{L}$	$\mathcal{U}$
B_{up}/Hb_{up}	$(H - h)/2$	U_{up}
B_D/Hb_D	D	U_{up}
B_{cav}/Hb_{cav}	D	U_s

3. First flow features by cross-comparison experiments/simulations

160 In this part, we perform a first characterization of common flow features observed in both experiments and numerical simulations. We focus in particular on the geometry of the dead zone in the cavity and a so-called *boundary layer* in the yielded zone.

3.1. Stress fields and dead zone

165 Upstream of the cavity, the incoming channel flow corresponds to a classical stationary viscoplastic Poiseuille flow [8, 3]. Hence, shear stress is maximum at the wall, and linearly decreases away from it. An unyielded moving plug is present in the center of the channel.

Figures 3 and 4 show the typical patterns of stress fields and unyielded zones observed inside the cavity. In spite of the noise present on experimental data, the similarities between the results obtained in simulations and in experiments are evident. In both cases, the shear stress τ_{xy} presents a maximum that generally follows a slightly curved path close to the top of the cavity (indicated by the black curve in Fig. 3), while the normal stress τ_{xx} shows a distinct pattern below or above the maximum of τ_{xy} . In particular, the sign of $\partial_x \tau_{xx}$ is opposite in the two regions. A continuous unyielded plug is observed in the center of the channel, while a static unyielded dead zone forms at the bottom of the cavity. In the simulations, thanks to the high accuracy of the numerical scheme, the two yield surfaces, denoted by 170 $y = y_{int}(x)$ (interface with lower dead zone) and $y = y_{plug}(x)$ (interface with the plug), are easily identified as the positions where the values of strain rate vanish. In experiments, the location of the dead zone $y_{int}(x)$ can be determined precisely from the images (see Fig. 1). The determination of the upper plug $y_{plug}(x)$ is more difficult, as it is strongly sensitive to the errors on 175 velocity measurements. Reliable values of y_{plug} could be obtained only at cavity center $x_{1/2}$ (through a fit of the longitudinally-averaged velocity profile), such that the position of the upper plug in Figure 4 is only indicative.

To compare quantitatively the shape of the dead zone formed in the cavity in simulations and in experiments, we computed the shape factor 180 $\Phi = A_{tot}/(D|y_{int}(x_{1/2})|)$, where $A_{tot} = \int_0^D |y_{int}(x)|dx$ is the area of yielded material in the cavity and $y_{int}(x_{1/2})$ corresponds to the deepest position of the solid-liquid interface. As shown in Figure 5, it is observed that Φ is essentially constant for all the configurations studied, in both experiments and simulations. This is indicative of a shape-invariance property of the yield

Figure 3: Numerical simulations: colormaps of normal and shear stress τ_{xx} and τ_{xy} (case $D = 1.5$ cm, $h = 3$ cm for fluid F4). Colorbar values in Pa. The thick black curve represents the location of the maximum of τ_{xy} or, equivalently, the upper limit of the boundary layer $y_s(x)$ (see text). The gray areas correspond to the unyielded zones. Note that the maps represent a zoom-in view of the viscoplastic boundary layer above the cavity. The lower and upper channel walls are not shown.

Figure 4: Experiments: same as Fig. 3 (case $D = 1.5$ cm, $h = 3$ cm with fluid F4 and a flow rate $Q = 15.3$ cm³/s). The upper unyielded zone has been traced on the basis of the determination of y_{plug} at cavity center $x_{1/2}$ and is only indicative. As in Fig. 3, the maps represent a zoomed-view of the viscoplastic boundary layer above the cavity.

195 interface, independently of cavity length and depth. Note that this result is necessarily restricted to the case of relatively *small* cavity lengths, for which

the yield interface does not reach cavity bottom. For very long cavities, we expect $y_{int}(x_{1/2}) \rightarrow h$, and thus $\Phi \rightarrow 1$. In addition, it is observed that the values of Φ are comprised within the same range ($0.7 - 0.8$ typically) in numerical and experimental results (Fig. 5), thereby showing the similarity of the interface shape in both cases.

Figure 5: Shape factor of the solid-liquid interface Φ (see definition in text) as a function of viscoplastic numbers B_{up} or Hb_{up} . Glyphs correspond to Table 1, while colors legend are indicated in Figure 2. Left: simulations. Right: experiments.

3.2. Flow zones

Figure 6 presents typical profiles of longitudinal velocity u and shear rate $|D(\mathbf{u})|$ at $x = x_{1/2}$ in the simulations. Note that $|D(\mathbf{u})| = |\partial_y u|$ at this location. By symmetry, only the first half of the profiles is shown. Qualitatively, these profiles were found to display similar features in all the simulations performed. The velocity profile shows a characteristic sigmoidal shape, increasing from 0 at the interface with the lower dead zone to a maximum in the upper plug zone. The shear-rate profile is bell-shaped, with a well-defined maximum in between. Remark that the profile is generally non-symmetric with respect to its maximum. The location of the shear rate maximum is denoted by y_s . Similarly, to simplify the notations, the positions of the lower and upper yield surface at $x_{1/2}$ will henceforth be denoted by y_{int} and y_{plug} , respectively (Fig. 6). Lastly, the velocity at $(x_{1/2}, y_s)$ is denoted by U_s ¹.

¹The s index is reminiscent of the "slip" nomenclature used in [15]. We remind that this nomenclature is not related to the *slipline theory* for plastic solids (as described in [17]).

Figure 6: Numerical simulations: Typical cross-section profiles of longitudinal velocity u (top, in cm.s^{-1}) and shear rate $|D(\mathbf{u})|$ (bottom, in s^{-1}) at $x = x_{1/2}$, the middle of the cavity (y in m) (fluid F3, same parameters as in Fig. 7). By symmetry (see section 2.2 for details on the geometrical configuration of the simulations), only the lower halves of the profiles are shown. Note the sharpness of $|D(u)|$ at the interfaces between the yielded and unyielded zones, indicative of the high-quality numerical resolution.

215 Based on these profiles and the observation of stress fields (see section 3.1), we distinguish between three different zones in the flow:

- a zone of width δ_{BL} between y_{int} and y_s , which we will refer to as the *boundary layer*,
- a zone of width δ_{PL} between y_s and y_{plug} , which we will refer to as the *Poiseuille-like layer*,
- 220 • the moving plug zone above $y = y_{plug}$.

Note that the definition of boundary layer introduced here is slightly different from that used in [9, 4, 16], where this terminology referred to the whole yielded zone. Instead, as will be discussed later, we found it relevant in our

225 case to limit the boundary layer to the zone in which the shear rate, and consequently the shear stress, increase. The terminology of Poiseuille-like layer for the stress-decrease zone situated above, comes from the observation of a quasi-linear decrease of shear stress in this zone, exactly as in the incoming Poiseuille flow upstream of the cavity [8].

Figure 7: Experiments: Typical vertical profiles of longitudinal velocity u (top) and shear rate $|D(u)|$ (bottom) at $x = x_{1/2}$, the middle of the cavity (fluid F3 with $D = 1.5$ cm, $h = 1.5$ cm and $Q = 6.4$ cm.s $^{-1}$, like in Fig. 6). The location y_s of the maximum of $|D(u)|$ is determined on the smoothed profile (dashed curve, see text), while the corresponding uncertainty δy_s accounts for the difference with the maximum of the unsmoothed values (symbols).

230 As shown in Figure 7, velocity and shear-rate profiles at $x = x_{1/2}$ obtained in the experiments present similar shapes, such that similar flow zones can be defined. When the shear rate is computed from measured velocity profiles through a simple finite-difference scheme, the peak in the shear rate profile

is sometimes less marked than in the simulations, with the existence of an
 235 apparent plateau around the maximum (well visible in Fig. 7). However,
 if a smoothing procedure is applied on velocity profiles prior to computing
 the derivative (3^{rd} -order polynomial fit over moving windows of 21 points),
 a single shear rate maximum is retrieved. Observe that the smoothed shear-
 rate profile remains consistent with unsmoothed data points if error bars are
 240 taken into account. As explained in [8], plateaus in unsmoothed shear-rate
 profiles were generally observed for the largest cavity lengths D . Whether
 these plateaus represent a true physical feature, or are due to measurement
 errors, remains to be elucidated. In [8] possible correlations between the
 width of these plateaus and viscoelastic rheological properties of Carbopol
 245 were investigated, but no definitive conclusion could be drawn. In the present
 study, since the numerical simulations (which account for a genuine viscoplas-
 tic rheology) never exhibit such plateaus, we decided to base our analyses
 of experimental data on the smoothed shear-rate profiles. This allows us to
 uniquely determine y_s and U_s (Fig. 7) and directly compare these quantities
 250 to their numerical counterparts. Error bars associated to these quantities
 are determined to reflect the differences with the non-smoothed case (and
 hence the robustness of the values with respect to the smoothing procedure
 adopted).

Finally we note that even though later analyses will mostly focus on quan-
 255 tities defined at $x_{1/2}$, the zoning introduced above can be defined along the
 whole length of the cavity. In numerical simulations, the position $y = y_s(x)$
 of maximum shear rate, or equivalently of maximum shear stress, can be
 determined for all values of x (accounting in this case for the complete ex-
 pression of $|D(\mathbf{u})|$). A typical example is shown in Figure 3 (see also Fig. 14).
 260 The boundary layer, comprised between $y_{int}(x)$ and $y_s(x)$, generally presents
 a lentil shape, with a thickness progressively vanishing at cavity edges. Inter-
 esting also is that $y_{plug}(x)$ seems to follow the shape of the boundary layer. In
 experiments, the precise determination of $y_s(x)$ all along the cavity is more
 difficult, due to the relatively large noise level on $|D(\mathbf{u})|$ -values as soon as
 265 spatial averaging cannot be applied. Remark nevertheless that the overall
 shape of the boundary layer appears qualitatively similar to that observed
 in the simulations (see Fig. 4).

3.3. Dead zone interface

Figure 8 shows the evolution of dead zone interface depth y_{int} in simula-
 270 tions and in experiments. In both cases, it is observed that y_{int} significantly

decreases with cavity length D (Fig. 8 - insets). Furthermore, as shown in the main panels, the ratio $|y_{int}|/D$ appears to roughly follow power-law trends with the viscoplastic numbers B_D or Hb_D defined on the basis of incoming flow velocity U_{up} and cavity length D (see Tab. 2). In the simulations, the trend is consistent with Oldroyd's scaling, namely $|y_{int}|/D \propto B_D^{-1/3}$. Similarly, in experiments, the power-law trend is consistent with an exponent of $-1/(n+2)$ corresponding to the Herschel-Bulkley version of Oldroyd's scaling [4]. We remark nevertheless that the dispersion of data points around these main trends remains significant, particularly in the experimental case. Even in numerical results, variations of $|y_{int}|/D$ of more than 50% can be observed for a given value of B_D or Hb_D . Hence, although correctly describing the main trend, Oldroyd's scaling is insufficient to quantitatively capture the location of the yield interface in the configurations studied here. Note also that the larger deviations observed in the experimental case could be due to more complex rheological features of Carbopol. In particular, these deviations may be related to the slight asymmetry of the interface shape, presumably due to viscoelasticity, reported in [8].

Figure 8: Dead zone interface scaled by cavity length $|y_{int}|/D$ as a function of viscoplastic numbers B_D or Hb_D in log scales (insets: y_{int} as a function of D). Beware of the slightly different vertical scales on both plots. Glyphs correspond to Table 1, while colors legend are indicated in Figure 2. Left: simulations. Dashed line indicates the power law $B_D^{-1/3}$. Right: experiments. Dashed line indicates the power law $Hb_D^{-1/(n+2)}$, with $n = 0.4$.

3.4. Flow characteristics at the boundary layer interface

We recall that the boundary layer denotes in our case the zone of stress increase observed in the cavity between the dead zone and the quasi-Poiseuille

flow zone above (see Fig. 6). As shown in Figure 9, a linear relation is found, both in experiments and in simulations, between the velocity U_s measured at the boundary layer interface and the plug velocity in the incoming channel U_{up} . Interestingly, the slope of this linear relation appears to be close to 0.4 in both cases. The velocity at boundary layer interface U_s thus appears to be essentially controlled by the incoming flow, independently of cavity characteristics.

Figure 9: Flow velocity at boundary layer interface U_s versus plug velocity in the incoming channel flow U_{up} . Glyphs correspond to Table 1, while colors legend are indicated in Figure 2. Left: simulations (dashed line of slope ≈ 0.39). Right: experiments (dashed line of slope ≈ 0.44).

Similarly the maximum stress τ_m , which is measured on the boundary layer interface, appears to be directly related to incoming flow characteristics. Figure 10 shows the existence of a linear relation between τ_m and the stress on the wall τ_w in the incoming channel. In both experiments and simulations, the data appear to follow $\tau_m \approx 0.8\tau_w$. Furthermore, since the incoming flow obeys a viscoplastic Poiseuille equation, the ratio τ_w/τ_y is itself directly related to the incoming viscoplastic number B_{up} or Hb_{up} . Accordingly, a good correlation is also observed between τ_m/τ_y and B_{up} or Hb_{up} in both simulations and experiments (Fig. 10).

3.5. First conclusions

The results shown above confirm the agreement between the numerical simulations and the experiments, despite the different viscoplastic constitutive laws considered in the two cases. In particular, comparison of the two

Figure 10: Top: Shear stress at boundary layer interface τ_m as a function of wall shear stress τ_w in the incoming channel. Dashed lines represent the relation $\tau_m = 0.8\tau_w$. Bottom: Ratio τ_m/τ_y as a function of the viscoplastic number B_{up} or Hb_{up} , with additional log-log representation in inset. Left: simulations. Right: experiments. data sets allows us to exhibit consistent trends that appear to be characteristic of the flow configuration under study. First, in the range of moderate viscoplastic numbers investigated here, a zoning of the flow in the cavity can be defined by distinguishing between the stress-increase and the stress-decrease layers. Unlike the situation at high values of the viscoplastic number, the shear-rate and shear-stress profiles in these two zones are not symmetric. The stress-decrease zone corresponds to a Poiseuille-like flow layer, while the stress-increase zone delimits a boundary layer in the vicinity of the dead zone. As a further evidence of the asymmetry between these two layers, Figure 11 shows that the thickness of the Poiseuille-like zone δ_{PL} (measured at $x_{1/2}$)

is generally significantly larger than the thickness of the boundary layer δ_{BL} (except for the longest cavities), again in both experiments and simulations.

Figure 11: Ratio of Poiseuille-like zone thickness over boundary layer thickness, δ_{PL}/δ_{BL} as a function of viscoplastic number B_{up} or Hb_{up} . Left: simulations. Right: experiments. Glyphs correspondence is indicated in Table 1. For the colors legend, see Figure 2.

Second, the location of the dead zone interface y_{int} appears to be only poorly captured by Oldroyd's scaling, which is expected to hold at high values of the viscoplastic numbers (see section 1). Even if global power-law trends with B_D and Hb_D are visible in the data, a large dispersion is present in both simulations and experiments. Interestingly, however, good correlations are observed between flow velocity and shear stress at the interface of the boundary layer and the characteristics of incoming channel flow (in particular B_{up} and Hb_{up}). Hence, the effective *boundary condition* felt by the Poiseuille-like flow layer appears to be essentially controlled by the incoming flow, independently of cavity characteristics. In the following, we shall focus in more details on the properties of the boundary layer, with the objective to better identify the factors controlling its extension.

4. Extended scaling for the boundary layer

4.1. Boundary layer equation

Following the detailed analysis of Balmforth *et al.* [4], we studied whether Oldroyd's viscoplastic boundary layer equation is verified, at least approximately, in the flow configurations studied here. In the geometry under consideration, Oldroyd's equation writes:

$$2\partial_x\tau_{xx} + \partial_y\tau_{xy} = 0. \quad (4)$$

Thanks to the high resolution of our simulations, we can numerically study the derivatives of the stress fields and check how precisely Eq. (4) is verified in the yielded zones. Spatial fields of both terms of Eq. (4) are shown in Figure 12 for a typical example. It is indeed observed that Oldroyd's equation seems to be verified within a few percents in the whole flow zone, and in particular for the profile at the center of the cavity $x_{1/2}$ (bottom-right of Fig. 12).

340

Figure 12: Assessment of Oldroyd's equation from the results of numerical simulations (case $D = 1.5$ cm and $h = 3$ cm for fluid F4): colormaps of the different terms of the equation, and vertical profiles at $x_{1/2}$.

More quantitatively, we systematically compared the L^1 averages of the

345 terms of Eq. (4), namely:

$$L_{Old}^1 = \frac{1}{y_{plug} - y_{int}} \int_{y_{int}}^{y_{plug}} |2\partial_x \tau_{xx} + \partial_y \tau_{xy}|(x_{1/2}, y) dy, \quad (5)$$

$$L_{Txx}^1 = \frac{1}{y_{plug} - y_{int}} \int_{y_{int}}^{y_{plug}} |\partial_x \tau_{xx}|(x_{1/2}, y) dy, \quad (6)$$

for all the flow configurations simulated. These averages are shown in Figure 13 as a function of the incoming flow viscoplastic number B_{up} . As expected, L_{Old}^1 decreases when B_{up} increases. Observe however that L_{Old}^1 remains always significantly smaller than L_{Txx}^1 , and reasonably close to zero, for all the simulations performed. It can thus be concluded that Oldroyd's
 350 equation is reasonably verified even in the regimes of moderate Bingham number considered in this study.

Figure 13: L^1 averages defined in Eqs. (5) and (6), nondimensionalized by D/τ_y , as a function of Bingham number B_{up} for all simulations performed: L_{Txx}^1 (with empty glyphs) and L_{Old}^1 (with filled glyphs).

4.2. Generalized scaling for boundary layer thickness

Previous section showed that the flow zone above the cavity obeys a viscoplastic boundary layer equation even at moderate values of the viscoplastic number. Yet recall that, unlike at high viscoplastic numbers [4], the location of the yield interface y_{int} is only poorly captured by an Oldroyd's scaling in our results (see Fig. 8). We hypothesize that this apparent paradox is due to the absence of symmetry of the shear-rate and shear-stress profiles in

Figure 14: Sketch recalling the definition of the boundary layer considered in this study and the associated characteristic variables used for the new scaling proposed (see text). The upper limit of the boundary layer corresponds to the maximum of the shear stress (black curve). The colormap is the same as in Figure 12(bottom-left): magnitude of the stress derivatives involved in Oldroyd’s boundary layer Eq. (4).

the flow zone. We thus checked whether a more consistent scaling emerges when considering only the stress-increase zone, namely the *boundary layer* defined in our case. Assuming that the proper velocity scale for this layer is the value U_s at boundary layer interface (Fig. 14), we defined yet another Bingham number, B_{cav} , based on U_s and cavity length D (see Tab. 2). As shown in Figure 15, the normalized thickness δ_{BL}/D does indeed appear to be univocally related to B_{cav} . All simulated points nicely collapse on a single trend consistent with a generalized Oldroyd’s scaling:

$$\frac{\delta_{BL}}{D} \propto B_{cav}^{-1/3}. \quad (7)$$

Recall that U_s was shown to be correlated to incoming flow velocity U_{up} (Fig. 9). Accordingly, from the above relation between δ_{BL} and B_{cav} , we could also expect the existence of a relation between δ_{BL} and the classical Bingham number B_D defined on the base of U_{up} [4]. In practice, however, it appears that the correlation of δ_{BL}/D with B_D (not shown) is far less good than with B_{cav} , suggesting that the observed relation between U_s and U_{up} is only approximate. The Bingham number B_{cav} appears to represent the best control variable for the boundary layer thickness in our case.

Similarly Figure 16 shows that, in spite of a larger dispersion due to measurement errors, a good correlation is observed in experimental results between δ_{BL}/D and the Herschel-Bulkley number Hb_{cav} defined on the basis

Figure 15: Numerical simulations: evolution of normalized boundary layer thickness δ_{BL}/D as a function of Bingham number B_{cav} (left) and $B_{cav}^{-1/3}$ (right). Dashed line has a slope of ≈ 0.52 . Glyphs correspondence is indicated in Table 1. For the colors legend, see Figure 2.

of U_s and D (Tab. 2). Here also, all the data are consistent with Herschel-Bulkley version of Oldroyd's scaling, which writes:

$$\frac{\delta_{BL}}{D} \propto H b_{cav}^{-1/(n+2)}. \quad (8)$$

These results justify *a posteriori* the appellation of boundary layer for the stress-increase zone in our results. Recall that this boundary layer is bounded by an unyielded zone on only one of its sides, and thus typically corresponds to half of the boundary layer defined in [4].

Finally, Figure 17 shows that, unlike δ_{BL} , the thickness of the Poiseuille-like layer δ_{PL} does not seem to follow an Oldroyd's scaling. Correlations between δ_{PL}/D and B_{cav} or Hb_{cav} are relatively poor in both simulation and experimental results. This confirms that, although Oldroyd's equation is also verified, the Poiseuille-like layer does not behave as a boundary layer in the flow regime studied here. Observe nevertheless that correlations between δ_{PL}/D and B_{cav} or Hb_{cav} seem to improve for the largest values of the viscoplastic numbers investigated (hence the lowest values of $B_{cav}^{-1/3}$ and $Hb_{cav}^{-1/(n+2)}$), which may be indicative of a progressive transition towards the

Figure 16: Experimental results: evolution of normalized boundary layer thickness δ_{BL}/D as a function of Herschel-Bulkley number Hb_{cav} (left) and $Hb_{cav}^{-1/(n+2)}$ (right). Dashed line has a slope of ≈ 0.45 . Glyphs correspondence is indicated in Table 1. For the colors legend, see Figure 2.

375 asymptotic regime in which the whole flow zone behaves as a viscoplastic boundary layer.

5. Final remarks

The results obtained in this study lead to generalize the notion of viscoplastic boundary layer previously introduced at high values of the viscoplastic numbers to describe the flow layer forming between two unyielded zones. We show that, at moderate values of the viscoplastic numbers, only the portion of the flow layer in which the shear rate and shear stress increase (see Fig. 14), effectively behaves as a boundary layer. In this case, this boundary layer ensures the transition between the unyielded dead zone that forms in the cavity and the fully-developed, Poiseuille-like flow zone above. Interestingly however, the thickness of this boundary layer is found to follow the same Oldroyd's scaling as that obtained in the asymptotic regime, providing adapted definitions of the viscoplastic numbers are introduced. Note also that this boundary layer actually corresponds to the so-called *shear band* introduced in [16], with the difference that we provided here a detailed description of the dynamics (velocity and shear-rate profiles) inside this layer.

Figure 17: Evolution of normalized Poiseuille-like layer thickness δ_{PL}/D as a function of viscoplactic number $B^{-1/3}$ or $Hb_{cav}^{-1/(n+2)}$. Left: simulations. Right: experiments. Glyphs correspondence is indicated in Table 1. For the colors legend, see Figure 2.

These results call for an extension of viscoplastic boundary layer theory at smaller values of the viscoplactic numbers B and Hb . Since the same boundary layer equation appears to be verified, the main difference with the situation at high viscoplactic numbers appears to be the lack of symmetry of the shear-rate profiles in the flow zone. A more accurate description of the velocity and shear-rate profiles would therefore need to be worked out in order to adapt the developments performed in [4]. A proper investigation of the transition towards the asymptotic regime, in which symmetric shear-rate profiles are recovered and the whole flow zone behaves as a boundary layer, also represents an interesting prospect for future work.

Finally, we want to stress that the detailed cross-comparison between experimental and numerical results performed here, constituted a fruitful approach to exhibit features and trends that can be regarded as characteristic of the viscoplastic rheology. In experiments, real yield-stress fluid frequently present additional rheological properties (*e.g.* viscoelasticity in the case of Carbopol), which, combined with measurement errors, tend to add dispersion to data and blur the trends. Numerical simulations based on finely-resolved meshes and non-regularized schemes do not suffer from this limitation, and provide insights into variables (*e.g.*, stress fields) that are difficult to access

experimentally. Since the simulations are based on specific viscoplastic constitutive laws, comparisons with experiments remains nevertheless necessary to ensure that the features highlighted numerically, *e.g.* here the viscoplastic boundary layer, are also visible in the *physical world*. We argue that such an intertwined dialog between experimental and numerical results represents a promising venue to advance knowledge on the flow of yield-stress materials in complex configurations, notably when coexistence between yielded and unyielded zones is involved.

Acknowledgments

We thank the Referees for their comments which contributed to improve the quality of the article. This work is done within the framework of an INFINITI *structuring project* of the *Mission pour l'Interdisciplinarité* of the CNRS, which is here acknowledged. This project, Visco3Plug, was funded by the CNRS, France, in 2017 and 2018. Numerical simulations were done using computer resources of the Pôle Scientifique de Modélisation Numérique (PSMN), Lyon, France.
