16

17 **Abstract**

18 Measuring displacement-length profiles along normal faults provides crucial information on fault growth processes.
19 Here, based on satellite imagery and topography we analyze 357 normal faults distributed along the active rift of
20 Dabbahu-Manda-Hararo (DMH), Afar, which offers a unique opportunity to investigate the influence of magmatism on
21 fault growth processes. Our measurements reveal a large variety of slip profiles that are not consistent with elastic
22 deformation. Their analysis contributes towards a better understanding of the lateral propagation of faults, especially
23 when nucleation points and existence of barriers are included. Using the fault growth model of Manighetti et al. (2001),
24 we determine the preferred direction of lateral propagation for each fault. Our results suggest that lateral propagation of
25 faults is easier away from areas where magma has been stored for long time at crustal depth, and has thus modified the
26 thermo-mechanical properties of the host-rock. However, these areas correspond also to areas where the initiation of
27 fault growth appears as easiest along the rift. In combining these results with the analysis of rift width and the position
28 of magma reservoirs along DMH rift, we show that fault growth keeps track of the magma presence and/or movement
29 in the crust.

31

32

33 1. Introduction

34 Process of fault growth has been studied from earthquake surface ruptures as well as from cumulative slip profiles for
35 various styles of tectonic deformation (Pollard and Segall, 1987; Walsh and Watterson, 1988; Cowie and Scholz,
36 1992a,b; Dawers et al., 1993; Bürgmann et al., 1994; Cartwright et al., 1995; Cowie and Shipton, 1998; Manighetti et
37 al., 2001a, 2004, 2007, 2015; Scholz, 2002; Klinger, 2010). Most models are based on the elastic theory and for an
38 isolated normal fault, they predict that slip should be maximum at the center of the fault and should tend towards zero at
39 both ends of the fault trace, following an elliptical profile (Pollard and Segall, 1987; Cowie and Scholz, 1992a; Scholz,
40 2002). However, the numerous slip profiles measured from natural exposures, show a larger variety of patterns, with a
41 first-order linear, and often, asymmetric shape (Muraoka and Kamata, 1983; Peacock and Sanderson, 1991; Bürgmann
42 et al., 1994; Dawers and Anders, 1995; Nicol et al., 1996, 2010; Contreras et al., 2000; Manighetti et al., 2001a, 2004,
43 2015; Davis et al., 2005; Roche et al., 2012; Nixon et al., 2014; Tibaldi et al., 2016). Several mechanisms have been
44 proposed to explain such a discrepancy between observations and model predictions. First, interactions of adjacent fault
45 segments leading to the development of a main fault by segment linkage could cause a scattering of the cumulative slip
46 along multiple fault traces (Cartwright et al., 1995; Dawers and Anders, 1995; Nicol et al., 1996, 2010; Fossen and
47 Rotevatn, 2016). Second, the heterogeneity of the friction on the fault interface may contribute to the relaxation or
48 concentration of stress along the fault plane and therefore locally stop or promote slip along the fault (Mikumo and
49 Miyatake, 1978; Bürgmann et al., 1994). Third, interactions between faults, as well as crustal heterogeneities, act as
50 barriers to fault propagation, promoting vertical fault growth instead (Aki, 1979; King, 1986; Manighetti et al., 2001a,
51 2004). In this latter case, the scarp height measurement represented as a function of the distance along the fault and
52 called “displacement-length profile” or “slip profile”, may thus be considered as a source of information regarding the
53 conditions of lateral fault propagation and they can be used as a proxy to record the different phases of growth of a
54 fault.

55 The Afar Depression is an ideal place to study the long-term evolution of normal faults because both low erosion and
56 sedimentation make the normal faults well preserved, allowing for the use of the scarp height as a suitable measure of
57 the cumulative slip. Manighetti et al. (2001a) used displacement-length profiles measured on normal faults dissecting
58 the surface of the Afar depression to propose a model of fault growth based on the shape of profiles, especially those
59 showing linear sections. The study of Manighetti et al. (2001a), however, did not take into account the potential
60 influence of the magmato-tectonic interactions on the fault growth, whereas all the faults are located in a highly
61 volcanic context. Indeed, the influence of magma bodies on the fault activity has been observed both at short and long
62 time scales in Afar, and in other extensional regions (Mastin and Pollard, 1988; Rubin and Pollard, 1988; Rubin, 1992;
63 Gudmundsson, 2003; Gudmundsson and Loetveit, 2005; Doubre et al., 2007; Doubre and Peltzer, 2007; Calais et al.,
64 2008; Biggs et al., 2009; Medynski et al., 2013, 2016). Along the Dabbahu-Manda-Hararo (DMH) rift, in central Afar,

magmato-tectonic interactions have been proved active for the last hundred thousand years (Lahitte et al., 2003a,b; Vye-Brown, 2012; Ferguson et al., 2013; Medyski et al., 2013, 2015, 2016). Using interferometric synthetic aperture radar analysis (InSAR) together with field observations, magmato-tectonic interactions have also been evidenced on the short-term, over the 5 years long-lasting rifting episode from 2005 to 2010, during both the dyking injections (Wright et al., 2006; Rowland et al., 2007; Grandin et al., 2009, 2010b; Hamling et al., 2009) and the few month-long post-dyking periods (Dumont et al., 2016).

DMH rift is in a late phase of magmatic continental rifting where dyke intrusions are assumed to be the main process for the nucleation and growth of normal faults (Carbotte et al., 2006; Rowland et al. 2007; Ebinger et al. 2013). Therefore, its past and recent magmato-tectonic activity makes it a good case study to examine the interplay between magmatism and faulting, and to investigate how faults propagate along an active magmatic rift. Here we use high-resolution remote-sensing data and topography to map in detail normal fault scarps in the DMH rift and to measure cumulative throw along fault strike for 357 faults. By analyzing the shape of the displacement-length profiles as well as their distribution along DMH rift with respect to the magma reservoirs, we aim at better understand fault growth processes in presence of magma. More specifically we look how magma-induced heterogeneities in the crust can promote, or inhibit, lateral fault development. We also show that displacement-length profile for each fault can be used to track past magma injections.

2. Geological Setting

The Afar Depression is a diffuse triple junction where three divergent plate boundaries meet: the oceanic ridges of the Red Sea (RS), the Gulf of Aden (GA), and the East African Rift Systems (EARS) (Fig. 1a; Barberi and Varet, 1977; Tesfaye et al., 2003). On-land continuations of the GA and RS oceanic ridges are not yet connected and they overlap in central Afar (Courtillot et al., 1980, 1987; Tapponnier et al., 1990; Manighetti et al., 1997, 1998, 2001b). Along these two branches, active extension and recent volcanism are concentrated along rift segments, whose size and morphology are similar to those of second order segmentation of an oceanic slow-spreading ridge (Hayward and Ebinger, 1996; Manighetti et al., 1998), although continental breakup is not yet clearly established in Afar (Makris and Ginzburg, 1987; Tiberi et al., 2005; Hammond et al., 2011).

Insert Figure 1

The DMH rift belongs to the RS ridge (Fig. 1a). It consists in a ~60 km-long and ~20 km-wide volcano-tectonic segment that localized faulting and volcanism since ~1-1.5 Myr (Hayward and Ebinger, 1996; Manighetti et al., 2001b; Lahitte et al., 2003b; Audin et al., 2004). The DMH rift segment concentrates most of the extension accommodating the divergent motion of the Nubia and Arabia plates, which are moving apart at a rate of 15 mm/yr (Fig. 1a; e.g. Vigny et al., 2006). Similar to other rift segments in Afar, the DMH encompasses a central volcanic center, the Ado'Ale Volcanic

97 Complex (AVC) characterized by silicic rocks, which was intensely dismantled by large normal faults (Fig. 1b; Lahitte
98 et al., 2003a,b). The location of the AVC corresponds to where the azimuth of the DMH rift axis and associated fault
99 systems changes significantly. South of AVC, the main graben and normal faults are oriented $\sim$ N150°, i.e. orthogonal to
100 the N055°-oriented Arabia/Nubia divergent plate motion. North of AVC, the faults and the rift inner graben are oriented
101 N165° (Fig. 1b; Rowland et al., 2007; Medynski et al., 2013).

102 At its northern tip, the DMH rift hosts the $\sim$ 10 km in diameter Dabbahu stratovolcano (Fig. 1b). This volcano has
103 participated in resurfacing the topography north of AVC, as suggested by extensive lava flows emitted 72-58 kyrs ago
104 (Medynski et al., 2013). Geodetic and seismic data have shown that the Dabbahu, as well as the nearby Gabho volcano,
105 were involved in the first and largest dyke intrusion ($\sim$ 60 km long) of the 2005 rifting episode (Wright et al., 2006;
106 Ayele et al., 2007; Grandin et al., 2009). The analysis of both historical eruptions and InSAR data following the
107 September 2005 intrusion suggests the existence of a series of stacked sills located below the Dabbahu volcano, at depth
108 ranging from 1 to 5 km. Consistency of depth between the two approaches indicates that this magma storage could be a
109 long-lived source (Field et al., 2012).

110 During the rifting episode, the dykes injected between June 2006 and May 2010 were exclusively fed by the mid-
111 segment magma chamber (MSMC) located at the rift center, $\sim$ 5 km south of the intersection between the AVC chain and
112 the rift axis, where the crust has been stretched and thinned down to 6 km (Keir et al., 2009; Hamling et al., 2009, 2010;
113 Grandin et al., 2010a, b; Belachew et al., 2011). Modeling of geodetic data spanning inter-dyking periods has suggested
114 that MSMC consisted both of a shallow magma chamber ($\sim$ 4 km depth) and of a deeper one ($>$ 15 km) (Grandin et al.,
115 2010a; Hamling et al., 2009). Most of the smaller intrusions (at most $\sim$ 15km long) propagated unilaterally towards
116 either the northern or the southern end of segment (Hamling et al., 2009, 2010; Grandin et al., 2010b, 2011, 2012;
117 Belachew et al., 2011, 2013), in a similar manner to what was observed during the Krafla rifting episode in Iceland
118 (Björnsson et al., 1979; Wright et al., 2012). Normal faulting above dykes has been proposed to be the main process of
119 seismic energy release during dyke intrusions (Belachew et al., 2013) and also to be responsible for the low-frequency
120 earthquakes (Belachew et al., 2011; Tepp et al., 2016). Seismic analysis revealed that northward propagating dykes were
121 faster and more voluminous than southward propagating ones. Several mechanisms have been proposed to explain these
122 differences in the migration rates as resulting either from asperities associated with previous dyke intrusions, or
123 subcrustal magma chamber (Belachew et al., 2011), or an asymmetry in the distribution of tensile stresses along the rift
124 (Grandin et al., 2009, 2011; Barnie et al., 2015). In addition, MSMC refilled between dyke injections, inducing
125 significant transient surface displacements at the center of the rift (Grandin et al., 2010b) and triggering slip along the
126 surface faults during the months following the injections (Dumont et al., 2016). The lateral extension of the MSMC is
127 poorly constrained, although at first-order it should range between 5 km and 8 km along-axis (Grandin et al., 2010a;
128 Belachew et al., 2011). In addition to these reservoirs, the inversion of magneto-telluric data collected along a west-east

129 profile located north of AVC has suggested the presence of a large magma reservoir located mostly off-rift, extending ~
130 30km to the west, ranging from 5 and 10km in depth (Desissa et al., 2013).

131

132 **3. Materials and Method**

133 Using panchromatic Quickbird images (resolution 60 cm, acquired between January 2006 and May 2007), SPOT-5
134 images (resolution 2.5 m, acquired between October 2005 and January 2006), a 10 m-accuracy DEM generated from
135 SPOT-5 stereo images (resolution 20 m) and InSAR data spanning the post-Sept. 2005 period (resolution 20 m), faults
136 were mapped along the DMH rift (Fig. 1b; Grandin et al., 2009; Dumont et al., 2016).

137 Among this fault population, we only consider individual faults longer than 500 m, in order to exclude incipient faults,
138 and also because small scarps are falling into the limit of the vertical accuracy of the DEM. In addition, most of the
139 short faults are located within the inner floor of the rift and may be partially covered by lava flows that would lead to a
140 misinterpretation of their displacement-length profile. Following this criterion, our dataset is composed of 357 normal
141 faults (Fig. 1b).

142 Using SPOT-5 DEM, we have extracted the cumulative vertical throw along strike for each fault in our dataset, by
143 estimating the height of the scarp for a series of parallel short profiles normal to each fault strike, following the
144 methodology described in Dumont et al. (2016). The scarp height represents therefore cumulative slip that includes the
145 September 2005 intrusion and the centimeter-scale deformation until January 2006 induced by slow magma transfers
146 (Dumont et al. 2016). The short profiles are separated by ~15 m, and the total number of profiles for each fault depends
147 on the total length of the fault.

148 Each profile for our fault population has been normalized using both their maximum displacement ($D/D_{\max}$) and their
149 maximum length ($L/L_{\max}$) to be classified according to Manighetti et al. (2001a). These authors distinguished eight types
150 of slip profile based on their shape, which are grouped into three main categories: unrestricted, restricted and elliptical
151 profiles (Fig. 2). The scenario they proposed for fault growth takes into account the initiation point, where slip starts,
152 and barriers, where propagation stops. The first-order linear profiles would eventually become elliptical, as a result of
153 fault growth evolution that includes both a vertical development and a bilateral propagation. Asymmetrical slip profiles
154 appear when a barrier is encountered along one (half-restricted and tip-restricted profiles, Figs. 2b,c) or both fault tips
155 (double tip restricted (DTR) profiles, Figs. 2d-f). Faults are thus unilaterally propagating or vertically developing,
156 respectively. Steep gradients reflect early arrest in the lateral growth. Finally, the elliptical profiles are interpreted as
157 profiles of faults that are not propagating anymore (Fig. 2g). However, when elliptical profiles show some tapering at
158 one end (Fig. 2h), it is interpreted as the evidence that lateral propagation of the fault has resumed after a phase of
159 vertical growth, after passing the barrier.

160 Insert Figure 2

161 4. Results

162 4.1 Patterns of Displacement-Length Fault Profiles

163 The fault population in the DMH rift is composed of ~40% of pinned faults, e.g DTR category, of 30% of propagating
164 faults including either bilateral or unilateral growth, and of 30% of faults considered to be at their final stage of
165 development, e.g. having an elliptical profile (Fig. 2). In this latter category, the elliptical profiles with tapers (~17%)
166 indicate a new phase of lateral growth. It means that about half of the population studied is still in a phase of lateral
167 propagation, while the second half is in a phase of vertical growth (Fig. 2). This analysis also reveals that two third of
168 the 357 faults under study have encountered at least one barrier during their lateral growth (Table 1).

169 The restricted patterns represent almost half of the fault population under study (Figs. 2d-f and Table 1). Faults with a
170 restricted displacement-length profile show longer and higher scarps than unrestricted faults (Table 1), which is
171 consistent with a later stage of development (Manighetti et al., 2001a). Most of the restricted displacement-length
172 profiles are asymmetrical (88%, Table 1) and clustered in DTR2 and DTR3 groups (Figs. 2e and f). The steep decrease
173 of slip for the restricted profiles occurs over a distance that is variable, although it never exceeds 20% of the total length
174 of the fault. DTR3 profiles differ from DTR2 by their steepest gradient: their maximum slip occurs at a distance of 10%
175 to 20% of the total fault length, whereas it occurs at one third of the total fault length for DTR2 (Fig. 2e), reflecting a
176 different timing of their meeting with a barrier.

177 Regarding the profiles consistent with unrestricted patterns, most of them (84%) correspond to an asymmetric shape,
178 with one steep slip gradient on one side of the fault, e.g. half-restricted or tip-restricted profiles (Figs. 2b and c). They
179 are considered as unilaterally propagating and they represent 22.4% of the total population of 357 faults. The steep
180 gradient of the unrestricted category never affects more than 20% and 10% of the total length of the fault for the half-
181 restricted faults and the tip-restricted, respectively (Figs. 2b and 2c). Half-restricted faults are twice as more frequent
182 and shorter than tip-restricted ones, and they also show lower D_{max} (Table 1). On the contrary, the group of unrestricted
183 profiles consists in a small population (4.2%) that includes the shortest faults (Figs. 2a and Table 1). This group
184 corresponds to young faults that have small dimensions and that are still bilaterally propagating.

185 Insert Table 1

186 Considering the elliptical category, the proportions of profiles with tapers and those of quasi-elliptical ones are
187 relatively similar. The figure 2h shows how variable can be the length of the tapered tip of elliptical patterns, which can
188 represent up to 50% of the fault length. Although elliptical displacement-length profiles are interpreted to correspond to
189 mature faults, their dimensions (D, L) are smaller than those of the restricted category, which gathers the longest faults
190 with the largest cumulative displacement (Table 1). Even though lengths of unrestricted and elliptical faults are
191 comparable, the maximum displacement for each category differs significantly with larger displacements for the
192 unrestricted category (Table 1).

193 4.2 Unilaterally propagating faults

194 In this section, we examine lateral propagation with a focus on tip-restricted and half-restricted patterns, as they both
195 represent a later stage of growth, the bilateral propagation corresponding to the first phase of fault growth (Manighetti et
196 al., 2001a).

197 Insert Figure 3

198 The Figure 3 shows the location of the half-restricted and tip-restricted profiles along the DMH rift. For each fault, a
199 symbol (point/square) is indicating which side of the fault is locked and does not propagate anymore. Faults are rather
200 evenly distributed within the axial depression and, to a lesser extent along the rift shoulders, even though they are
201 slightly more numerous at the rift center, in the AVC area (Fig. 3). A small group of mainly northward propagating
202 faults is also observed off-axis, at $\sim 12.3^\circ\text{N}$ and at ~ 9 km eastward from MSMC. From these observations, it appears
203 that most of the propagating faults are located along the inner floor and within the topographic depression.

204 The overall spatial distribution of both half-restricted and tip-restricted displacement-length profiles indicates that 63%
205 of the faults located south of MSMC are southward propagating, whereas 58% of those located north of MSMC are
206 northward propagating (Fig. 3). In the northern part of the rift, the northward propagating faults are located within the
207 rift topographic depression and do not extend further east than the September 2005 dyke-induced graben. We note that
208 most of the active faults confined within the narrow 2005 graben are propagating southward.

209 Finally, the off-axis position of the northward propagating faults located east of the MSMC, suggests that these
210 unilaterally propagating faults might have been formed during an earlier phase of DMH rifting during which the
211 conditions of magma supply were certainly different to now (Ebinger et al., 2013). Such displacement-length profiles
212 detected off-axis, on the eastern part of AVC, could also be interpreted such that this area is still affected by extension
213 processes. We will not discuss further these faults.

214

215 4.3 Growing faults and rift geometry

216 Here we focus on the influence of magmatic processes on the fault growth, first by considering the distribution of the
217 fault length along the rift, and second by combining these results with observations related to rift geometry.

218 Insert Figure 4.

219 We address such matters by considering all 357 faults regardless of their displacement pattern (Fig. 4): The longest
220 faults (> 3 km) are equally distributed along the borders of the inner floor and the rift shoulders, but 70% of them are
221 located south of AVC with respect to the small caldera (40.59°E , 12.34°N) located at the intersection between AVC and
222 DMH rift (Fig. 4). In the rift center and vicinity of AVC, the density of short faults is high. South of AVC, the short
223 faults appear relatively equally distributed along the axial depression and, to a lesser extent, along the rift shoulders.
224 Further north, the short faults are also numerous above the September 2005 dyke-induced graben.

225 Insert Figure 5.

226 In the figure 5, we consider both the inner floor depression and the depression extended to the rift shoulders, to define
227 the first-order rift width. This figure shows that the narrowest part of the whole rift coincides with the intersection of
228 AVC with DMH rift. From there, the rift width broadens towards both rift tips. However, this widening is not similar
229 north and south of AVC. This is even more apparent when the rift shoulders are included in the evaluation of the width
230 of the rift. South of AVC the rift is the largest, ~8 km (up ~20 km when rift shoulders are included), whereas the rift
231 width is ~6 km North of AVC (up to ~8 km, rift shoulders included). The analysis from figures 4 and 5 suggests that at
232 the rift center, where recent and old magma centers are located, the relative large population of short faults concentrates
233 in the narrowest part of the rift. On the contrary, at the rift tips, the axial depression is wider and composed of longer
234 faults. In addition, the faults are more widely distributed in the southern half of the rift (Fig. 4).

235

236 **5. Discussion**

237

238 Confronting the displacement-length fault profiles with morphological considerations at the scale of the rift points at the
239 interactions between magmatic and tectonic processes at different spatial scales. We have shown that most of the
240 propagating faults are located within the topographic depression, where most of the active extension occurs, mostly
241 accommodated by dyke intrusions (Carbotte et al., 2006; Rowland et al., 2007; Ebinger et al., 2013). In addition, most
242 of the barriers appear to be located towards or in the vicinity of magma storage such as the MSMC, suggesting that
243 faults preferentially propagate away from the magma reservoir. Hence, we suggest that here volcanic centers play a key
244 role on the development and the later evolution of the tectonics structures (Fig. 3). More generally, we have
245 demonstrated the co-location of intense crustal deformation and area of permanent magma storage (Figs. 4-5). In view
246 of these observations, fault growth processes along the DMH rift seem to be controlled by local processes such as
247 magmatism, and not only by regional stress conditions, as it has been proposed for the Asal rift (Fig. 1b, Manighetti et
248 al., 2001a).

249 As suggested by the topography and geology of the DMH rift (Varet and Gasse, 1978; Vye-Brown et al., 2012),
250 magmatism along DMH rift is the predominant feature (Fig. 1b): the highest elevation at the rift center is associated
251 with the rhyolitic AVC and two volcanoes are located at the northern rift tip: the Dabbahu and Gabho. Both were
252 involved into the transfer of magma below the rift axis during the 2005 dyking event (Wright et al., 2006; Ayele et al.,
253 2009; Grandin et al., 2009). Furthermore, a small caldera, located at the intersection between the rift axis and the AVC,
254 indicates the existence of a magma chamber partly drained about 20 kyrs ago (Fig. 1b; Medynski et al., 2015). Contrary
255 to the caldera and AVC, MSMC does not show any volcanic feature or edifice at the surface and it was only evidenced
256 by geodetic and seismic data (Keir et al., 2009; Hamling et al., 2009, 2010; Grandin et al., 2010a, b; Belachew et al.,

257 2011). However, MSMC, the small caldera, and AVC, they all are, or have been, associated with the presence of magma
258 storage that has been maintained between 12.28°N and 12.4°N of latitude during the last ~20 kyrs (Medynski et al.,
259 2015; Fig. 1b), area that might be extended based on magneto-telluric results. These along-axis variations in the
260 location of magma bodies could reflect a plumbing system composed of short-lived reservoirs, whose positions may
261 vary locally although they remain confined close to the rift center, similar to the localized and transient magma bodies
262 of the second-order slow spreading centers (Cannat et al., 1995; Carbotte et al., 2015). Such distribution of magma at
263 crustal depth participates in making the crust particularly heterogeneous.

264 More specifically, the presence of magma reservoirs or lenses at shallow depth modifies the thermal field and
265 consequently the temperature-dependent chemical equilibriums in the surrounding crust. The magma-induced thermal
266 anomaly is dissipated by thermal conduction through the upper crust, inducing a thermal softening of the host-rock,
267 which in turn creates a weak layer or a viscoelastic shell (Pavlis, 1996; Burov et al., 2003; Regenauer-Lieb et al., 2008).
268 The thickness of this low-viscosity shell directly relates to the temperature regime of the host-rock, and to the shape and
269 volume of the reservoir (Currenti and Williams, 2014; Douglas et al., 2016 and references therein). The mechanical
270 properties of this weak layer, and more precisely the Young modulus, are significantly decreased when compared to the
271 brittle host-rock (Kampfmann and Berckhemer, 1985; Hobbs et al., 1986). By relaxing the local stresses, this low-
272 viscosity layer induces an increase in the strain-rate along shear zones (Regenauer-Lieb et al., 2008), whereas the brittle
273 host-rock outside the shell keeps accumulating stresses (Currenti and Williams, 2014). The resulting strength contrast
274 between the brittle crust and the viscoelastic shell promotes the conditions of failure in the host rock, hence the
275 localization of the deformation in the upper crust (Benes and Davy, 1996; Callot et al., 2001; Corti, 2003; Buck, 2006;
276 Currenti and Williams, 2014). The shear failure in the host-rock is further enhanced by the presence of a deflating or
277 inflating magma chamber (Gerbault et al., 2012; Currenti and Williams, 2014 and references therein). Therefore, taking
278 into account the probable presence of numerous distinct magma bodies below the region delimited by AVC and MSMC,
279 although some are likely not active anymore, the thermo-mechanical conditions of the upper crust in this area appear
280 highly favorable for the initiation of fault growth (Figs. 4 and 6). In addition, these conditions that facilitate the
281 localization of deformation take place in the narrowest part of the rift (Figs. 4 and 5), where the brittle-ductile transition
282 (BDT) is the shallowest (Grandin et al., 2012). However, the localization of the deformation has probably not been
283 primarily induced by magma bodies such they are currently distributed in the upper crust. Actually the shallow depths
284 of the BDT and the load of a large volcanic edifice such AVC, associated with a weak layer, could have certainly
285 contributed to localize deformation in this area since a long time period according to analog experiments of van Wyk de
286 Vries and Merle (1996).

287 Insert Figure 6

288 The low-viscosity shell surrounding the magma body is characterized by pressure and temperature changes when

289 considered with respect to the host-rock. These variations make the energy state of the low-viscosity shell higher than
290 the one of the host-rock. More specifically, temperature increase participates in the process of energy dissipation that
291 gives rise to temperature feedback effects, and therefore contributes to strain localization (Regenauer-Lieb et al., 2008).
292 In fact, an increase of temperature causes a decrease of viscosity that generates an increased strain-rate, which in turn
293 produces an increase in temperature (shear heating) and close the loop of self-localizing temperature feedbacks (Hobbs,
294 1986; Regenauer-Lieb et al., 2008). Small temperature perturbations caused for instance, by phase changes or chemical
295 reactions, are sufficient to trigger temperature feedbacks, making them a fundamental instability in the crust, even if
296 they are time dependent and therefore short-term effects (Regenauer-Lieb et al 2008). Thus, such processes can account
297 for a self-sustaining localization of deformation and contribute to maintain crustal heterogeneities even on a relative
298 short-term, both in regions of long-term magma storage and in areas where magma is only temporarily transferred, for
299 instance by dyke intrusions (Fig. 6). In this way, the thin band of southward propagating faults located within the
300 September 2005 dyke-induced graben north of AVC (Fig. 3), may reflect the effect of infrequent intrusions injected
301 from three interacting magma sources (Dabbahu, Gabho and MSMC) under the eastern rift shoulder, as illustrated by
302 the first rifting event in September 2005 (Fig. 3, Wright et al., 2006, Ayele et al., 2009; Grandin et al., 2009), a kind of
303 event that may also have occurred in the past (Fig. 6, Medynski et al., 2016).

304 Although the thermo-mechanical heterogeneities within the brittle crust promote the initiation of faults, they also act as
305 barriers to fault propagation, as illustrated by the only few long faults and conversely, the large number of short faults
306 that are located at the rift center (Fig. 4), as well as by the location of the steepest gradient along the propagating faults
307 (Fig. 3, Manighetti et al., 2004). In addition, the inelastic deformation due to the highly damaged crust located at the
308 fault tips is susceptible to prevent the lateral propagation of the faults (Manighetti et al., 2004). This higher density of
309 barriers located at the rift center is seen both at fault and rift scale (Figs. 3-5). These numerous and various sources of
310 heterogeneities in the upper crust may explain why the elliptical profiles, which have been proposed to correspond to a
311 late stage of fault growth, have smaller dimensions than the restricted ones (Table 1). Indeed, if the elliptical profiles
312 represent mature faults, their conditions of growth along DMH rift may have been somehow laborious, so that both their
313 lateral and vertical development have been inhibited.

314 Conversely, transfers and storage of magma at shallow depth affect less often the rift tips or at greater depths as
315 highlighted in Asal rift (Pinzuti et al., 2010). It makes these areas more stable from a thermo-mechanical point of view.
316 There, the lithosphere is relatively colder, the BDT is up to twice deeper than at the rift center (Fig. 6, Grandin et al.,
317 2012) and the rift is wider (Fig. 5). Therefore, the conditions for fault propagation appear more favorable than at the rift
318 center, as shown by the lower density of faults, although longer, at the rift tips, and especially at the southern one (Figs.
319 3, 4 and 6). We propose that the better localization of deformation observed north of AVC is related to the interaction
320 between the DMH rift and the Dabbahu volcano.

321 Finally, the analysis of cumulative-slip profiles combined with geometrical observations are compared to results
322 obtained for a shorter-time scale, during the last rifting episode. Similarly to the propagating faults, the dykes
323 propagated from the magma reservoir towards the rift tips. However, significant differences were detected in the
324 seismicity rates of dykes propagating northward or southward (Belachew et al., 2011; Grandin et al., 2011; Barnie et al.,
325 2015). These observations were interpreted as resulting either from the extensive stresses differently accumulated along
326 the rift (Grandin et al., 2009, 2011; Barnie et al., 2015) or from asperities associated with magma (Belachew et al.,
327 2011). Our long-term analysis revealed in some way comparable results as the brittle deformation is differently
328 localized north and south of AVC-MSMC region. Therefore, we propose that the pre-existing tectonic structures, better
329 localized in the northern part of the rift, could have contributed to a faster propagation of dyke in this area, in addition
330 to other processes suggested (Grandin et al., 2009, 2011; Belachew et al., 2011; Barnie et al., 2015).

331

332 **Conclusion**

333 We performed a detailed analysis on displacement-length profiles for 357 faults distributed along the Dabbahu-Manda-
334 Hararo rift (Afar). Our results suggest that areas under permanent influence of magma bodies gather favorable
335 conditions for initiating faulting (Fig. 6). However, because of the strong heterogeneities that magma bodies generate
336 within the crust, these areas do not offer reliable conditions for efficient lateral propagation of faults. Hence, we find
337 there a majority of short faults. Persistent self-localizing temperature effect is expected where magma is stored and
338 where dykes are injected and faults activated. On the contrary, the deeper brittle-ductile transition and the relative cooler
339 lithosphere near the rift tips are less affected by magma transfers and therefore offer better condition for lateral
340 propagation (Fig. 6), although this might not be the case for the northern extremity of the rift, where the Dabbahu and
341 Gabho volcanoes may interact with normal faults through dyke injections. This analysis shows that the propagating
342 faults keep track of the magma transfers within the crust, suggesting that most of the dykes along the axial depression
343 are mostly fed by the MSMC. On the contrary, the northeastern rift shoulder is mostly intruded by dykes, such as in
344 September 2005, whose magma was provided by the reservoirs of Dabbahu and Gabho volcanoes, even if these events
345 are recognized as unusual.

346

347 **Acknowledgment**

348 We thank Harsha Bhat and Raphaël Grandin for fruitful discussions. We are grateful to C. Ebinger and A. Tibaldi for
349 their comprehensive reviews that helped to improve the paper, and to the Editor, C. Passchier for his handling of the
350 manuscript. Most figures were prepared using the Generic Mapping Tool (GMT) software by Wessel and Smith (1991)
351 and Inkscape. This research was supported by the French Agence Nationale pour la Recherche (DoRA project, ANR-09-
352 JCJC-0051-01). This is IGP contribution number 3811.

 583
 584
 585
 586 Figure 1: (a) Afar Depression with the different propagating rift segments corresponding to the branches of the triple
 587 junction with the Red Sea extending from the North, the Gulf of Aden ridge penetrating the depression from the SW and
 588 the East African Rift Systems in the South. Direction of propagation (arrow symbols) is indicated after the tectonic
 589 model from Manighetti et al. (1998, 2001b). (b) The 357 faults studied are mapped along Dabbahu-Manda-Hararo rift.
 590 The lateral extension of the shallow magma chamber (MSMC) involved in the 2005-2010 rifting episode is proposed
 591 after Grandin et al. (2010b). The Ado'Ale silicic (AVC) complex forms a volcanic chain transverse to the rift axis.
 592 Distinct directions of extension result from Vigny et al. (2006) and McClusky et al. (2010) models (indicated closed to
 593 the vectors) but only those obtained from McClusky et al. 2010 show a small change along the rift as they consider the
 594 relative motion between the Nubia plate and the Danakil microplate.
 595
 596
 597 Figure 2: Distribution of displacement-length profiles for the 357 normal faults studied along the Dabbahu-Manda-

598 Hararo rift following the classification of Manighetti et al. (2001a). These eight shapes are split into three categories of
599 faults: the unrestricted ones which are uni- or bilaterally propagating (a-c), the restricted faults which are pinned faults
600 characterized by a vertical growth phase (d-f), and the elliptical faults (g-h). See text for more details.

601
602 Figure 3: (a) Location of faults with half and tip restricted displacement-length profiles along the Dabbahu-Manda-
603 Hararo rift. The high slip gradients along the faults are indicated by a circle and a square for the tip-restricted and the
604 half-restricted profiles, respectively. Faults in black propagate northward, while red faults propagate southward. In
605 background, the topography is shown with contour lines every 30 m. The borders of the topographic depression are
606 indicated by purple and gray lines (a and b respectively), and the September 2005 dyke-induced graben boundaries in
607 light gray lines (a) and in red shading (b). The red star locates the current shallow reservoir MSMC involved in the
608 2005-2010 rifting episode. The red fill circle (b) locates the Dabbahu volcano reservoir. (b) Interpretative scheme
609 showing the directions of lateral propagation deduced from the half-restricted and tip-restricted profile patterns.

610
611
612 Figure 4: Distribution of the length for the 357 faults studied, all patterns included. The first three colors represents
613 faults with length shorter than 1, 2 and 3 km respectively. The red star indicates the position of the most recent shallow
614 reservoir MSMC and the gray dotted lines the borders of the topographic depression. The small caldera is located by a
615 red circle. The caldera separates faults located north and south of AVC.

616
617
618 Figure 5: (a) Spatial evolution of the rift width based on the geometry of the axial topographic depression (straight
619 lines) or the topographic depression extended to the rift shoulders (dashed lines). The background represents the DEM
620 (with contour lines every 30 m) and the 357 faults considered in this study. The red stars correspond to the current and
621 shallow magma reservoirs. (b) Interpretation of the spatial variations of the rift width, with the narrowest area (orange
622 circle) matching with the intersection between DMH rift and AVC that is under the permanent influence of magmatic
623 processes.

624
625 Figure 6 : Conceptual model illustrating the influence of magma on fault propagation. Some displacement-length
626 profiles are indicated with a dot showing the steepest gradient associated with the first barrier encountered during the
627 lateral propagation of the faults. Orange shading shows the 2005 dyke intrusion. The DMH rift is split into 3 sectors
628 reflecting the fault behaviors with respect to magmatic processes. The circular black arrows indicate where self-
629 localizing temperature feedbacks are expected. The brittle-ductile transition (BDT) is indicated after Grandin et al.

630 (2012). Below the figure, are detailed the faulting processes that are hindered (in blue), while in red are those that are
631 promoted.

632

633

634

635 Table 1: Characteristics of the fault classified into the eight categories presented in Figure 2. L_{mean} and D_{mean} for mean
636 length and mean maximum displacement respectively; L_{med} and D_{med} for median length and median maximum
637 displacements; « std » for standard deviation, « N » refers to the number of faults considered.
