Abstract—In this paper, we provide a comprehensive overview of the stochastic geometry framework explored extensively in literature to model and analyze the performance of communication networks. We provide a brief survey of the history of the approach, including recent applications to the analysis of several 5G enabling technologies. In the main technical section of the paper, we consider a case study in which we assume a system model where the idle mode capability is activated on base stations. A general expression of the coverage probability based on hypergeometric functions is then derived, yielding closed-form expressions that depend on the parity of the path loss exponent. Numerical results confirm the accuracy of our practical approximations.

I. INTRODUCTION

Enhanced capacity, improved service quality, lower power consumption, and ubiquitous coverage, are some of the most relevant objectives for the deployment of recent communication networks. The first step towards achieving these targets is an efficient approach to the modeling of these networks. In earlier years, modeling methods were mainly based on detailed geographical descriptions of the network; the accuracy of future results depended on the extrapolation of the actual state of the network for some evolution scenarios. To meet the expected demand, strategic planning must decide between a few potential architectures where costs and performance are assessed through detailed calculations. This approach, still adopted nowadays, generally requires the development of specific optimization softwares adapted to each network architecture, and relies on heavy, time-consuming, simulations [1], [2].

To address these limitations, tools from applied probability, particularly stochastic geometry (SG) and point process theory, have been introduced to model and analyze the communication networks [2]–[4]. SG provides a natural way to define and derive macroscopic properties for such networks, by averaging over all potential geometric models for the active nodes (mobile users, base stations in a cellular network, access points in a WiFi network, switching centers [5], ...), which often

capture the major dependencies between the network performance characteristics (connectivity, stability, capacity, ...) as a function of a relatively small number of parameters. In fact, a communications network can be viewed as a set of nodes, where locations can be seen as the realization of a point process in a given domain $\mathbb{R}^d$ [6]. At any given time, the signal received from the serving transmitter may be affected by the signals received from the other transmitters. The geometry of the locations of the nodes then plays a key role since it determines the signal-to-interference-plus-noise ratio (SINR) at each receiver and, subsequently, assesses the possibility of simultaneously establishing any collection of links at a given bit rate.

The seminal work in [2] provides a comprehensive understanding about the behavior of downlink cellular networks. By assuming that single-antenna base stations (BSs) are distributed according to a homogeneous Poisson point process (PPP), a cell association criterion based on the highest average received power, a single-slope path-loss model, and Rayleigh fading; the authors have obtained a tractable integral expression of the coverage probability. An important outcome is the SINR invariance property, which states that the SINR increases almost linearly with BS density to the point where noise becomes negligible; after which SINR remains stable and independent from the BS density. Another important outcome is a closed-form expression developed for the integral expression when the path loss exponent is equal to 4.

The motivation behind this paper is then to develop a closed-form expression for the coverage probability, which will encompass the expression in [2], and will be valid for all integer values of the path loss exponent. To do so, we explore the potential of hypergeometric functions analysis and consider a more general system model in which the idle mode capability (IMC) is activated on BSs.

The remainder of the paper is organized as follows. Section II introduces the contextual background of SG as a powerful tool for modeling communications networks and analyzing the performance of several 5th generation (5G) enabling technologies. Section III is the technical part of the paper,

in which we develop a general expression for the coverage probability that yields closed-form expressions depending on the parity of the path loss exponent. In Section IV, numerical results are reported to corroborate our theoretical findings and assess the accuracy of our approximations, and Section V concludes the paper.

II. STOCHASTIC GEOMETRY BASED APPROACH

In this section, we discuss basic insights to better understand the context of the SG approach. We briefly present the history of SG, address the fundamental concepts of modeling communication networks using SG, and summarize the state of the art of SG-based analysis for several 5G enabling technologies.

In fact, SG is an old branch of probability theory that deals with random geometrical structures such as point processes, random graphs, and random networks, as well as the challenging problems raised by their statistical analysis. The subject has progressed rapidly in response to the challenges from different applied sciences, from image analysis to communication networks.

In telecommunications, SG models are designed to capture aspects of wireless networks such as the association policy between users and nodes, interference characterization and interaction between nodes and/or users (repulsion, attraction, or zero interaction). The related research consists in analyzing these models with the aim of better predicting and controlling various network performance metrics.

A. Brief Historical Review

SG as a concept of geometric probability is a field with roots going back at least 300 years. In fact, the connection between probability theory and geometry can be traced back at least to the middle of the 18th century when Buffon's needle problem (1733), and subsequently questions related to Sylvester's four point problem (1864) and Bertrand's paradox (1889), started to challenge prominent mathematicians, and helped advance the probabilistic modeling. A short historical outline of these early days of geometric probability may be found in [7], [8].

Since the 1950s, the framework of geometric probability broadened substantially and has been framed as an academic area. In particular, the focus mainly switched to models involving a typical number of randomly selected geometric objects. As a consequence, the notion of point processes started to play a prominent role in this field, which since then was called "stochastic geometry". Simultaneously, relevant models were developed for wireless network technologies including mobile ad hoc networks, sensor networks, vehicular networks, and cognitive radio (CR) networks [9], [10].

Around the beginning of the 21st century, a number of new network technologies have arisen such as heterogeneous (HetNet) and millimeter wave cellular networks. SG has been extensively explored to develop models for these networks [2], [3] and then derive closed-form or semi-closed-form expressions for performance metrics and quality of service (QoS) indicators, without resorting to simulation methods or intractable deterministic models. The aforementioned metrics

and indicators are often based on concepts from information theory such as the SINR; which forms the mathematical basis for defining network connectivity and coverage.

B. Stochastic Geometry and the Modeling of Communication Networks

The contemporary network systems have a complicated multi-layer and multi-level architecture. Consequently, the network performance investigated for purposes of strategic planning and economic analysis is dependent on a large number of parameters, where it is generally difficult to determine in advance which are the main that mostly influence the desirable properties of the system. On the other hand, exhaustive simulations are time and resource consuming, and do not offer the ability to formally determine the structural parameters impacting the system.

SG resolves the aforementioned challenges by providing macroscopic network models that capture the essential spatial characteristics of networks performance and then economy through a lower number of structural parameters [1]. This way, the production function of telecommunication services can be analytically expressed where the main players in the network (subscribers/users, stations, links, mobiles) are considered as a realization of a family of stochastic processes belonging to simple parametric classes. Fig. 1 describes the typical architecture of a SG based model [1].

Fig. 1. A typical configuration of a stochastic geometry based model, where the distribution of users and nodes follows homogenous PPPs. The connections between nodes and users are shown in a single hierarchical level, and the cells boundaries form a Voronoi tessellation.

C. Stochastic Geometry and 5G Technologies

The 5G mobile communication networks are expected to be operational by 2020, many efforts and revolutionary ideas have been proposed and explored around the world to satisfy the increasing demand for higher data rates, lower network

latencies, better energy efficiency, and reliable ubiquitous connectivity. The primary technologies and approaches to address the requirements of 5G systems include:

- the densification of existing cellular networks with massive addition of small cells;
- peer-to-peer (P2P) communications enabling multi-network association (e.g., device-to-device (D2D) and machine-to-machine (M2M) communication enabled multi-tier HetNets);
- simultaneous transmission and reception (e.g., full-duplex (FD) communications);
- massive multiple-input multiple-output (massive MIMO);
- millimeter wave communication technologies;
- improved energy efficiency via energy-aware communication/design and energy harvesting;
- and new radio access techniques (e.g., non-orthogonal multiple access (NOMA)).

Fig. 2 describes the main components of a typical 5G network architecture.

Fig. 2. A typical architecture of a 5G network where small cells are modeled by aggregative point processes and macro cells are modeled by regular point processes.

Exploiting the power of SG, several notable results are obtained for cellular networks. For instance, the authors of [11] investigated the performance behavior of ultra-dense networks and confirmed that the SINR invariance property is no longer valid as the dual-slope path loss model is considered and the near-field path loss exponent is under the dimension of the network. Moreover, authors of [12], [13] revealed that antenna heights and omni-directionality are so detrimental to the network performance during ultra-densification. However, It is proved in [14] and references therein that the coverage probability has non-zero convergence in asymptotic regions of ultra-densification unless UE density grows unbounded.

On the other side, as the density of small cells increase is limited by a potential constraint on backhaul capacity, downloading contents from the core network via backhaul links becomes the bottleneck of the system, impairing the

throughput gain brought by the network densification. To overcome this, an innovative approach is considered where new cells, so-called *helper nodes*, are introduced into the network. These nodes have typically weak backhaul links and high capacity caches, so the content is retrieved locally instead of fetching it from the core network via backhaul links. Therefore, the backhaul link is used only to refresh the caches at off-peak times. Authors of [15] investigated the performance gain of a cache-enabled HetNet over a conventional HetNet with limited capacity backhaul.

The Massive MIMO technique exploring especially high number of antennas is characterized in [4], [16]. Since energy efficiency (EE) not only has great ecological benefits and represents social responsibility, but also has significant economic benefits, the authors of [17] apply tools from SG to analyze the energy efficiency of cellular networks through the use of the sleeping mode capability of BSs where the active or sleep mode of a BS is activated based on the cell load. In [18], the authors considered the energy harvesting where the system model consists of HetNet classes of self-powered BSs, which may differ in terms of the transmit power, deployment density, energy harvesting rate, and energy storage capacity. The objective was to characterize the regimes in which the self-powered network may have the same performance as the one with reliable energy sources. Extensions to the radio frequency (RF) energy harvesting is considered in the analysis in [19].

Based on dynamic spectrum access and spectrum sharing, CR technology is analyzed in [20] where a SG based analysis is considered for a combination of cognitive, energy harvesting and D2D based cellular network.

Recently, NOMA have received significant attention for the design of 5G radio access techniques. Unlike with the traditional orthogonal multiple access (OMA) techniques, where different users are served over orthogonal resource blocks, NOMA allows multiple users to share the same resource block. Based on SG, the baseline of a power-domain NOMA is investigated in [21].

From another point of view, securing communications is a critical issue for future 5G networks where there will be a great need for new wireless security mechanisms that do not necessarily rely on the usual bit-level protocols. Thus, based on the SG tractability, the physical layer security in the context of cellular networks and mmWave channel characteristics is discussed in [22].

III. COVERAGE ANALYSIS

In this section, we consider a downlink cellular network in which BSs and users are scattered according to two independent homogeneous PPPs Ψ and Ψ_u respectively with respective densities λ and λ_u . We assume that IMC is activated, then since users density is finite, ultra-densification will lead that some BSs will remain switched *on* with no users being served, hence these BSs may be put in idle state in order to mitigate the inter-cell interference and reduce the energy consumption. Based on the legacy of hypergeometric functions

analysis, we aim to develop a closed-form expression of the coverage probability in [2, Th. 2] by encompassing the Q -function based expression valid only for a path-loss exponent $\alpha = 4$.

We define the coverage probability p_c as the probability that the long-term SINR, is greater than a threshold T . It is equivalently the CCDF of SINR over the entire network and can be considered [2] as (i) the probability that a randomly selected user can reach a target T , (ii) the average fraction of users who reach T at any given time, (iii) the average fraction of the network area covered at any given time. Similarly, the concept of outage probability $p_o = 1 - p_c$ (CDF of SINR), is conceived as the probability of not being able to send a signal or symbol over a specific channel, and thus¹

$$p_c(T) = 1 - p_o(T) = \mathbb{P}\{\text{SINR} \geq T\}, \quad (1)$$

$$\text{where} \quad \text{SINR} = \frac{h l(r_0)}{l_{\text{agg}} + \sigma^2}, \quad (2)$$

h is the fading power of the channel between the typical user and the serving BS $\{b_0\}$, r_0 is the distance between the typical user and the serving BS assuming the nearest BS association policy, $l(r) = r^{-\alpha}$ is the path loss function such as α is the path loss exponent, σ^2 is the noise variance normalized by the BS transmit power P_{tx} , and $l_{\text{agg}} = \sum_{y_i \in \Psi \setminus \{b_0\}} g_i l(y_i)$ is the other-cell interference such as g_i is the fading power of the channels between the typical user and the interfering BSs.

We focus on the expression of p_c as the calculation of almost all the other metrics requires the preliminary calculation of p_c . In fact, the average ergodic rate τ may be seen as

$$\begin{aligned} \tau &\triangleq \mathbb{E}\{\ln(1 + \text{SINR})\} \\ &\stackrel{(a)}{=} \int_{t>0} \mathbb{P}\{\ln(1 + \text{SINR}) > t\} dt \\ &= \int_{t>0} \mathbb{P}\{\text{SINR} > e^t - 1\} dt = \int_{t>0} p_c(e^t - 1) dt \\ &= \int_{u>0} \frac{p_c(u)}{u+1} du \stackrel{(b)}{=} - \int_{u>0} \ln(1+u) \frac{\partial p_c(u)}{\partial u} du, \end{aligned} \quad (3)$$

where (a) follows from the property $\mathbb{E}\{X\} = \int_{t>0} \mathbb{P}\{X > t\} dt$ for a positive random variable X and (b) follows by applying integration by parts where $\lim_{u \rightarrow 0} p_c(u) = 1$ and $\lim_{u \rightarrow \infty} p_c(u) = 0$.

Moreover, in practical systems where a minimum operational SINR, namely γ_0 , is required, the constrained area spectral efficiency ASE_c is expressed as²

$$\begin{aligned} \text{ASE}_c &= \lambda \mathbb{E}\{\ln(1 + \text{SINR})\} \mathbb{1}(\text{SINR} \geq \gamma_0) \\ &= \lambda \int_{\gamma_0}^{\infty} \ln(1 + \gamma) f_{\Gamma}(\gamma) d\gamma \\ &= \lambda \left[\int_{\gamma_0}^{\infty} \frac{p_c(\gamma)}{1 + \gamma} d\gamma + \ln(1 + \gamma_0) p_c(\gamma_0) \right], \end{aligned} \quad (4)$$

¹ $\mathbb{P}(X)$ stands for the probability of the event X and $\mathbb{E}(X)$ for the expected value of the event X .

²The spectral efficiency is measured in nats/s/Hz, and need to be normalized by $\ln(2)$ to translate into bit/s/Hz.

where $f_{\Gamma}(\cdot)$ is the PDF of SINR observed at the typical user, and expressed as

$$f_{\Gamma}(\gamma) = \frac{\partial(1 - p_c(\gamma))}{\partial \gamma}.$$

Based on some standard assumptions, i.e. singular path-loss model, Rayleigh fading, BSs and users equipped with single antennas, and a cell association policy based on the highest average received power, the authors of [2] have obtained the following tractable expression of p_c

$$p_c(T) = \pi \lambda \int_0^{\infty} e^{-au^{\alpha/2} - bu} du, \quad (5)$$

where $a = T\sigma^2$ captures noise, $b = \pi \lambda [1 - (1 - p)(1 - {}_2F_1(1, -\delta; 1 - \delta; -T))]$ reflects interference such as $\delta = 2/\alpha$, ${}_2F_1(\cdot, \cdot; \cdot; z)$ is the Gauss hypergeometric function and p is the empty-cell probability, i.e. the probability that a typical user is associated to no mobile. p is generally approximated by averaging the void probability of Ψ_u over the distribution of a typical Voronoi cell area. Assuming a network deployed in the 2-D plane $\mathbb{R}^2$, the authors of [5] approximated p as

$$p \simeq \left(1 + \frac{\lambda_u}{3.5\lambda}\right)^{-3.5}. \quad (6)$$

Generally, the coverage probability in (5), cannot be formulated in closed-form expression. An exception is made when considering a path loss exponent of $\alpha = 4$ or assuming the interference-limited regime [2, Formulas (7) and (8)]. The following theorem develop a closed-form expression for p_c that is valid for every integer path loss exponent ≥ 3 .

Theorem 1. For integer path-loss exponents $\alpha \geq 3$, the coverage probability in (5) will be expressed in closed-form as

$$\begin{aligned} p_c(T) &= \frac{2\pi\lambda}{\alpha (T\sigma^2)^{\frac{2}{\alpha}}} \sum_{k=0}^{\frac{\alpha}{2}-1} \frac{(-1)^k \kappa^k}{k!} \Gamma\left(\frac{2+2k}{\alpha}\right) \\ &\quad \times {}_1F_{\frac{\alpha-2}{2}}\left(\frac{1}{\frac{4+2k}{\alpha}}, \dots, \frac{\alpha+2k}{\alpha} \middle| \frac{(-\kappa)^{\frac{\alpha}{2}}}{(\frac{\alpha}{2})^{\frac{\alpha}{2}}}\right), \end{aligned} \quad (7)$$

for α even, and as,

$$\begin{aligned} p_c(T) &= \frac{2\pi\lambda}{\alpha (T\sigma^2)^{\frac{2}{\alpha}}} \sum_{k=0}^{\alpha-1} \frac{(-1)^k \kappa^k}{k!} \Gamma\left(\frac{2+2k}{\alpha}\right) \\ &\quad \times {}_2F_{\alpha-1}\left(\frac{1}{\frac{2}{\alpha}} + \frac{k+1}{\alpha}, \dots, \frac{\alpha+k}{\alpha} \middle| \frac{4(-\kappa)^{\alpha}}{\alpha^{\alpha}}\right), \end{aligned} \quad (8)$$

for α odd, where

$$\kappa = \frac{1}{(T\sigma^2)^{2/\alpha}} \pi \lambda [1 - (1 - p)(1 - {}_2F_1(1, -\delta; 1 - \delta; -T))].$$

and ${}_pF_q(\cdot)$ is the generalized hypergeometric function, defined for complex parameters and argument by the series

$${}_pF_q\left(\begin{matrix} a_1, a_2, \dots, a_p \\ b_1, b_2, \dots, b_q \end{matrix} \middle| z\right) = \sum_{k=0}^{\infty} \frac{(a_1)_k (a_2)_k \dots (a_p)_k}{(b_1)_k (b_2)_k \dots (b_q)_k} \frac{z^k}{k!},$$

where $(a)_k$ is the Pochhammer symbol.

Proof. By the variable change of $x = au^{\alpha/2}$, the expression (5) of coverage probability can be rewritten as

$$\begin{aligned} p_c(T) &= \frac{2\pi\lambda}{\alpha a^{\alpha/2}} \int_0^\infty x^{\frac{\alpha}{2}-1} e^{-x} e^{-\kappa x^{2/\alpha}} dx \\ &= \frac{2\pi\lambda}{\alpha a^{\alpha/2}} \int_0^\infty x^{\frac{\alpha}{2}-1} e^{-x} {}_0F_0(.,.; -\kappa x^{2/\alpha}) dx. \end{aligned} \quad (9)$$

Depending on the parity of α , and using [23, Eq. (43)] which states for any natural number m that

$$\begin{aligned} {}_pF_q \left(\begin{matrix} a_1, a_2, \dots, a_p \\ b_1, b_2, \dots, b_q \end{matrix} \middle| z \right) &= \sum_{k=0}^{m-1} \frac{(a_1)_k (a_2)_k \dots (a_p)_k}{(b_1)_k (b_2)_k \dots (b_q)_k} \frac{z^k}{k!} \\ {}_{mp+1}F_{mq+m} \left(\begin{matrix} \overrightarrow{A_{1,k}}, \overrightarrow{A_{2,k}}, \dots, \overrightarrow{A_{p,k}}, 1 \\ \overrightarrow{B_{1,k}}, \overrightarrow{B_{2,k}}, \dots, \overrightarrow{B_{q,k}}, I_{1,k} \end{matrix} \middle| m^{(p-q-1)m} z^m \right), \end{aligned}$$

where for $j = 1, 2, \dots, p$ and $i = 1, 2, \dots, q$

$$\begin{aligned} \overrightarrow{A_{j,k}} &= \left(\frac{a_j + k}{m}, \frac{a_j + k + 1}{m}, \dots, \frac{a_j + m - 1 + k}{m} \right) \\ \overrightarrow{B_{i,k}} &= \left(\frac{b_i + k}{m}, \frac{b_i + k + 1}{m}, \dots, \frac{b_i + m - 1 + k}{m} \right) \end{aligned}$$

and

$$\overrightarrow{I_{1,k}} = \left(\frac{1 + k}{m}, \frac{2 + k}{m}, \dots, \frac{m + k}{m} \right)$$

Thus, for the even case, we choose $m = \alpha/2$, while for the odd case, we choose $m = \alpha$. Using the integral transformation of hypergeometric functions in [24, (1.7.525)], we get the desired result. $\square$

Note that the expression in [2, Th. 2] can be obtained directly from (7) where the Gaussian Q -function is expressed as

$$Q(x) = \frac{e^{-\frac{x^2}{2}}}{2} \left[{}_0F_0 \left(-; -; \frac{x^2}{2} \right) - \frac{x\sqrt{2}}{\sqrt{\pi}} {}_1F_1 \left(1; \frac{3}{2}; \frac{x^2}{2} \right) \right].$$

The accuracy of the analysis is discussed in the following section.

IV. NUMERICAL RESULTS

In Fig. 3, the coverage probability grows monotonically with the path loss exponent where the results of the expression from Theorem 1 are matching perfectly with the integration in (5).

In Fig. 4, the coverage probability decreases as the users process density λ_u increases, this may be explained intuitively by the observation that the average number of interfering BSs increases with users density due to the IMC activation. Moreover, it is interesting to mention that the SINR target T reduces the impact of users process density λ_u on the SINR CCDF. In fact, a lower T is generally common in the noise-limited regime where few BSs are deployed and therefore reduced impact of IMC activation (e.g., rural environments).

Fig. 5 shows the scaling of coverage probability with users density λ_u considering different values of BSs density λ and three formulations of the empty-cell probability p . The first

Fig. 3. The scaling of coverage probability with the path loss exponent α , the hypergeometric formulation of Theorem 1 is very tight with the integral expression where $\lambda = 0.7$, $\lambda_u = 0.2$, $\sigma^2 = 1$.

one is that of (6), the second is by considering the case of ultra-dense networks where $\lambda \gg \lambda_u$, in other words, a considerable increase in λ_u generates a corresponding increase in λ , and thus p may be approximated as

$$p = \left(1 + \frac{\lambda_u}{3.5\lambda} \right)^{-3.5} \simeq 1 - \frac{\lambda_u}{\lambda}. \quad (10)$$

Moreover, (10) may be seen as the first terms of an exponential Taylor expansion. Thus, we consider a third approximation of p in a more tractable way as $p \simeq e^{-\frac{\lambda_u}{\lambda}}$. The process of the transmitting BSs can then be approximated as a thinning transformation of density $\lambda e^{-\frac{\lambda_u}{\lambda}}$.

Note that the exponential approximation captures perfectly the trends of coverage probability under (6). In fact, p goes towards 0 as λ_u increases, i.e. BSs continually transmit signals, and the tagged user receives interference from all BSs, and then the coverage probability becomes independent from λ_u . However, under the second approximation (10), the coverage probability remains dependent on users density and goes towards 0 as λ_u increases.

V. CONCLUSION

The field of SG is rapidly evolving in conjunction with numerous ongoing developments from a variety of applications, and offers an interesting framework for the analysis of communication networks.

In this paper, we reviewed the context of SG based approaches and their application to the analysis of new 5G technologies. Moreover, the coverage probability under the IMC mode is investigated, and closed-form approximations are developed.

Our numerical results confirm that the hypergeometric expressions are perfectly matching with the numerical integration

Fig. 4. The scaling of coverage probability with the BS density λ for $\alpha = 4$ and different values of users density λ_u and SINR thresholds T .

Fig. 5. The scaling of coverage probability with the users density λ_u for different values of BS density λ and the empty-cell probability p . the solid line is for $p = (1 + (\lambda_u/3.5\lambda))^{-3.5}$, the dashed line is for the approximation of p by $\exp(-\lambda_u/\lambda)$, and the dotted line is for the approximation of p by $1 - (\lambda_u/\lambda)$.

when the path loss exponent is of integer value. The exponential approximation of the empty-cell probability is tight enough; particularly for low users densities.
