HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers. L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Porin self-association enables cell-to-cell contact in *Providencia stuartii* floating communities

*Institut de Biologie Structurale (IBS), University of Grenoble Alpes (UGA), Centre National de la Recherche Scientifique (CNRS), Commissariat à l'énergie atomique et aux énergies alternatives (CEA), 38000 Grenoble, France; †Life Sciences & Chemistry, Jacobs University, 28759 Bremen, Germany; ‡UMR 191, Aix-Marseille University, Institut de Recherche Biomédicale des Armées, Marseille, F-13385 Marseille, France; and ¶Laboratories of Excellence, Ion Channel Science and Therapeutics, 06560 Valbonne, France

The opportunistic pathogen *Providencia stuartii*, from the Enterobacteriaceae family (1), is involved in increasingly frequent infections in burn victims and patients undergoing long-term catheterization (2–5). Treatment of infections by *P. stuartii* is complicated by its intrinsically strong resistance to a wide range of antibiotics (4, 6–8) and by its ability to form biofilms. The latter may attach and grow on indwelling catheters (3, 9, 10) and on uroepithelial cells (11). Recently, we reported the microscopic characterization of *P. stuartii* plankton and biofilms and the unexpected finding that this species forms floating communities of cells in solution before its deposition as a surface-attached biofilm (12). Within floating communities, cells are in apparent contact and presumably stick to one another via protein–protein interactions (12). Inasmuch as the general diffusion porins are the most abundant proteins in the outer membrane (OM) of gram-negative bacteria, with a major porin often accounting for up to 70% of the OM protein content (up to 102 copies per cell) (13), we set out to verify whether *P. stuartii* porins could partake in the formation of floating communities.

Porins are water-filled channels spanning the OM of gram-negative bacteria (14) and constitute the principal entry route for hydrophilic nutrients, ions, and antibiotics into the periplasm. They are generally assembled as trimers, within which each monomer displays a conserved β-stranded architecture that delineates a hydrophilic channel. Substrate-specific porins are barrels of 18–26 β-strands, while porins governed by general diffusion (referred to as porins throughout the manuscript) feature 16 β-strands. In both cases, sifting properties are determined by the amino acid distribution at their constriction zone, contributed by the folding of extracellular loop L3 into the channel lumen. The genome of *P. stuartii* encodes two porins, Omp-Pst1 and Omp-Pst2. The uptake of β-lactams (cephalosporins and carbapenems, in particular), quinolones, and fluoroquinolones is mainly due to their passive diffusion through Omp-Pst1 (6, 7). Omp-Pst1 is essential to *P. stuartii* survival, while Omp-Pst2 promotes rapid growth, possibly through regulation of the cationic content of the periplasm (12).

The gram-negative pathogen *Providencia stuartii* forms floating communities within which adjacent cells are in apparent contact, before depositing as canonical surface-attached biofilms. Because porins are the most abundant proteins in the outer membrane of gram-negative bacteria, we hypothesized that they could be involved in cell-to-cell contact and undertook a structure-function relationship study on the two porins of *P. stuartii*, Omp-Pst1 and Omp-Pst2. Our crystal structures reveal that these porins can self-associate through their extracellular loops, forming dimers of trimers (DOTs) that could enable cell-to-cell contact within floating communities. Support for this hypothesis was obtained by studying the porin-dependent aggregation of liposomes and model cells. The observation that facing channels are open in the two porin structures suggests that DOTs could not only promote cell-to-cell contact but also contribute to intercellular communication.

Significance

We report that porins, the main gateway for hydrophilic nutrients and ions into bacterial cells, assemble face-to-face in crystals, yielding dimers of trimers (DOTs). Further investigation suggests that DOTs could support cell-to-cell contact in the floating communities formed by *Providencia stuartii*, and could enable direct communication between adjacent cells. Self-matching sterical zipper interactions are observed at the dimer interface, suggesting a means by which DOT formation could be restricted to cells of the same clonal origin.

the cell-to-cell contact property and that they could provide a means of direct communication between cells.

**Results**

**Structures of Omp-Pst1 and Its Complex with Maltose.** The structure of native Omp-Pst1 was solved in two space groups: C2 (type A; 3.2 Å resolution) and P2₁2₁2₁ (type B; 2.7 Å resolution) (SI Appendix, Table S1). In both crystal forms, the asymmetric unit contains a single trimer. In type A crystals, dimerization of trimers along the crystallographic twofold axis results in a DOT, assembled through steric zipper interactions between homologous segments in facing extracellular loops (Fig. 1A). In type B crystals, contact is also observed between extracellular loops but does not involve self-matching interactions. In both types of crystals, no contact is observed between intracellular turns, and complementary contact is established between transmembrane regions. The trimeric structures of Omp-Pst1 in type A and type B crystals are similar, superimposing with an rmsd of 0.356 Å over 1,056 residues. While extracellular loops of Omp-Pst1 are mostly folded as α-helices, the L5 extracellular loop of each monomer contributes a β-hairpin that is positioned over the channel’s extracellular vestibule and complicates access to the pore (SI Appendix, Fig. S1A). In type A crystals, the L5 β-hairpins are additionally involved in the crystal-packing interactions that underlie DOT assembly, at the unit cell level (Fig. 1A and B).

Compared with the canonical porins OmpF, OmpC, and PhoE from *E. coli*, Omp-Pst1 displays a similar pattern of charge distribution. In particular, the Omp-Pst1 channel is positively charged (+5e in Omp-Pst1 vs. +3e, +3e, and +6e in OmpF, OmpC, and PhoE, respectively) (Fig. 1I and SI Appendix, Fig. S2A), with a net charge of +5e. 

![Fig. 1](image-url)
charge of +1e at the constriction zone (0e, −2e, and 0e in OmpF, OmpC, and PhoE, respectively) (Fig. 1 A and L and SI Appendix, Fig. S2B). The electrostatic potential profile calculated along the channel of Omp-Pst1 indicates mild anion selectivity (Fig. 1L), in line with electrophysiology measurements and with molecular dynamics (MD) simulations based on this structure (15). Nevertheless, the Omp-Pst1 channel features more charged residues than E. coli porins (48%, 35%, and 20% more charged residues than OmpF, OmpC, and PhoE, respectively), suggesting higher translocation selectivity. The extracellular vestibule of Omp-Pst1 is negatively charged (Fig. 1 I and L).

In an attempt to determine whether or not Omp-Pst1 is involved in translocation of uncharged nutrients into the periplasm, a structure of a complex with maltose was obtained by soaking type B crystals in a mother liquor solution containing 100 mM maltose. The structure of the complex indicates electron density for three maltose molecules, that is, one per monomer, at an identical binding site. Specifically, residues from extracellular loops L1 (K31, E33), L3 (Q121), L6 (R251, G253), L7 (L300), and L8 (G337, N339) form a groove above the constriction zone within which each maltose establishes six to eight H-bonds (depending on the monomer), burying around 70% of its accessible surface (SI Appendix, Fig. S1B). The presence of a tight binding site at the channel entrance could underlie a role for Omp-Pst1 in the facilitated translocation of carbohydrates. Ensemble refinement of the maltose-bound Omp-Pst1 solving structures in L3 residue D117, positioned below the maltose binding site and above the channel constriction zone (SI Appendix, Fig. S1B).

Hence, D117 could participate in the translocation of maltose from its binding site in the extracellular vestibule to the periplasmic side. Moreover, in all Omp-Pst1 structures, a Ca2+ ion could be modeled at the interfacial cavity between the three monomers of the trimer, stabilized by cation–π interaction with the side chain of Trp59 from each monomer (SI Appendix, Fig. S3 A and B). Interestingly, this central cavity is opened to the intracellular side but is closed at the extracellular side by symmetrical interactions between Asn75 side chains from the three monomers. At the top of this cavity, an SO42− was modeled which appears to be stabilized by an anion–π interaction with the side chain of Trp59 from each monomer (SI Appendix, Fig. S3 E and F). Similar to Omp-Pst1, exposure of Omp-Pst2 to high Zn2+ concentrations leads to a dissociation of the trimer, suggesting a critical role for this central ion binding site in the regulation of Omp-Pst2 oligomerization (SI Appendix, Figs. S3 C and D). Furthermore, it shows that the central channel of Omp-Pst2 can accommodate both positively charged and negatively charged divalent ions.

**Omp-Pst1 and Omp-Pst2 Form DOTs Assembled Through Steric Zipper Interactions.** In Omp-Pst2 and in type A Omp-Pst1 crystals, packing is supported by the face-to-face interaction of two trimers via their extracellular loops, yielding DOTs (Fig. 1 A, B, E, and F). In both DOTs, the dimerization interface delineates a large negatively charged cavity (volumes of 30,610 and 37,959 Å3 for Omp-Pst1 and Omp-Pst2, respectively) (Fig. 1 I and J). The cavity of Omp-Pst2 is accessible from the bulk via three ellipsoidal fenestrations of 17 × 29 Å (Fig. 1 E, F, and J), while that of Omp-Pst1 is shielded from the bulk and presumably only accessible to water (Fig. 1 A, B, and J). The buried surface area per facing trimer are 921 Å2 for Omp-Pst1 and 1,215 Å2 for Omp-Pst2-DOTS—this is values above the threshold of 856 Å2 that has been proposed to discriminate between artificial and biological dimers in crystal structures (16). In comparison, the buried surface area per facing trimer is 350 Å2 in type B Omp-Pst1 crystals. The surface complementarity between facing trimers of the DOT is 0.40 for Omp-Pst1 and 0.64 for Omp-Pst2. The latter value is close to that displayed by antibody–antigen complexes, namely 0.65 (17).

The DOTs formed by Omp-Pst1 and Omp-Pst2 are singular in that they appear to be supported by steric zipper interactions—a structural motif that has, to date, been observed only in prions and amyloid fibers. Steric zippers form from the tight interdigitation of side chains emanating from equivalent residues in short self-matching sequences (4–11 residues) and they are, by nature, highly self-selective. In amyloid and prion assemblies, steric zippers associate β-sheets into highly ordered fibers (18, 19), but the steric zipper interfaces that form between facing monomers of Omp-Pst1 and Omp-Pst2 trimers are single layered. Thus, perhaps, neither Omp-Pst1 nor Omp-Pst2 would, if monomeric, be able to dimerize face-to-face through these motifs.

The steric zipper interfaces differ in the two porins. In Omp-Pst1, the three single-layered steric zipper interfaces are contributed by residues 206-GVVTSE-211 from extracellular loop L5 and would belong to the symmetry class III of steric zippers (face-to-face, up-down) (18) (Fig. 1 C and D), with a 15° tilt between the two facing β-strands. This interface is reinforced only by weak electrostatic interaction (distance between nonhydrogen atoms ≥3.5 Å) between K28 and D213 from facing extracellular loops L1 and L5, respectively (SI Appendix, Fig. S4A). The formation of Omp-Pst1 DOT thus appears fully governed by extracellular loop L5. In Omp-Pst2, residues 282-NLGNYG-287 from facing extracellular loops L7 interact via three single-layered nonaligned steric zippers that would correspond to the symmetry class I of steric zippers (face-to-face, up-up) (18) (Fig. 1 G and H). Each steric zipper interface, centered around residues G284 and N285, is complemented by a network of H-bonds which fastens extracellular loops L5, L7, and L8 from facing monomers (Fig. 1 G and SI Appendix, Fig. S5A). Of note, Omp-Pst1 features a 290-NLGNYG-295 sequence in its extracellular loop L7, similar to the 282-NLGNYG-287 sequence of Omp-Pst2. However, the L5 β-hairpin protrusion that contributes the 206-GVVTSE-211 steric zipper interface renders L7 inaccessible in Omp-Pst1 (SI Appendix, Fig. S1A). Nonetheless, N293, equivalent to Omp-Pst2 N285, plays an important role in Omp-Pst1 DOT formation, contributing two H-bonds to Y216 at the base of
the L5 β-hairpin which stabilize the latter and, therefore, the steric zipper interface (SI Appendix, Fig. S4A).
To evaluate the steric zipper propensity of Omp-Pst1 and Omp-Pst2 segments involved in their dimerization into DOTs, we crystallized the corresponding peptides. For each, we chose the smallest fragment hypothetically involved in the interaction: 206-GVVTSE-211 from Omp-Pst1, and 283-LGNY-286 from Omp-Pst2. Both peptides produced urchinlike microcrystals from which their structures were solved at 1.7 and 1.0 Å resolution, respectively (Fig. 2 and SI Appendix, Table S1). The two peptides display canonical cross-β structures, characterized by the in-register stacking of strands into β-sheets and by the mating of these sheets via a steric zipper, perpendicular to the fiber axis. Thus, both 206-GVVTSE-211 and 283-LGNY-286 have a high propensity to form steric zippers (Fig. 2) in isolation of their respective parent proteins. The 3D profile method (20) also identified these segments as highly prone to form steric zippers, with scores of −26.2 and −22.1 kcal/mol, respectively (SI Appendix, Fig. S6). They accordingly form fibrils in vitro (SI Appendix, Fig. S6 A and B).

Omp-Pst1 and Omp-Pst2 Self-Interact in Vitro. We investigated whether Omp-Pst1 and Omp-Pst2 can have adhesion properties in vitro. If so, incorporation of either porin into liposomes should lead to proteoliposome aggregation—a process we monitored by dynamic light scattering (DLS). We first examined phosphatidylcholine (PC) liposomes, whose surfaces are neutral at physiological pH. We used the direct-dilution method to incorporate porins into liposomes, enabling real-time monitoring of the process. Using centrifugation on sucrose gradient (21), we confirmed insertion of Omp-Pst1 and Omp-Pst2 into preformed liposomes, and observed that this process is favored at acidic pH (SI Appendix, Fig. S7). We then used DLS to monitor the average hydrodynamic radius of the proteoliposome aggregates which form, upon incorporation of Omp-Pst1 or Omp-Pst2 at increasing concentrations, into preformed liposomes (60-nm starting radius). We found that insertion of either porin into liposomes results in a fast (~30 to 45 s) and porin-concentration-dependent aggregation of proteoliposomes (Fig. 3 and SI Appendix, Fig. S8A). In contrast, incorporation of E. coli OmpF into PC liposomes by the same method had...
comparatively no effect on their average size distribution (SI Appendix, Fig. S8). The proteoliposome aggregation induced by Omp-Pst1 and Omp-Pst2 is visible in the pH 4 to 8 range, although it was reduced (smaller liposome aggregates) at pH 7 and 8, either due to a suboptimal incorporation of porins into liposomes at these pH values or to a reduced self-affinity (SI Appendix, Fig. S7).

To increase the stringency of further measurements, we nonetheless worked at pH 7, which avoided the formation of proteoliposome aggregates too large (>1 μm) and too polydisperse (>50%) to be resolved by our DLS instrument.

We ascertained the presence of Omp-Pst1 and Omp-Pst2 in proteoliposome aggregates by labeling lipids and porins specifically, and then by examining porin-induced proteoliposome aggregation using epifluorescence microscopy (SI Appendix, Fig. S8A). Omp-Pst1 and Omp-Pst2 were specifically labeled by engineering of a cysteine (Omp-Pst1-K221C and Omp-Pst2-K211C) at the C-terminal extremity of their L5 loop (SI Appendix, Figs. S4B and S5B, respectively), followed by derivatization of the resulting mutants with a maleimide-coupled green fluorophore (Alexa488). Fluorescent liposomes were prepared by introduction of a red fluorescent lipid (rhodamine derivative) in the bilayer composition. Both Omp-Pst1-K221C and Omp-Pst2-K211C retained the ability to induce proteoliposome aggregation in DLS experiments (SI Appendix, Fig. S8A). Furthermore, in epifluorescence micrographs, we observed a colocalization of the fluorescence signals arising from the lipids and the porins. The observation that the Omp-Pst1-K221C mutant can still self-associate indicates that the interface revealed by type B crystals is not relevant for proteoliposome aggregation, as the H-bond between K221(NZ) and N293(O) is central to this interface (SI Appendix, Fig. S4).

Aggregates of proteoliposomes formed at 2 μM porin concentration were examined by transmission electron microscopy, revealing stacks of lipid bilayers (SI Appendix, Fig. S9). Those aggregates display periodic order, further exemplifying the strong tendency of Omp-Pst1 and Omp-Pst2 porin to self-associate, both laterally and axially.

Additional DLS data were collected on liposomes composed of palmitoyl-oleyl (PO)PC and PO phosphatidylserine (POPS), in the presence and absence of rough and smooth lipopolysaccharides (LPSs). Data were collected at pH 7, at two liposome concentrations (0.125 and 1.25 mg/mL, corresponding to ∼2 and ∼20 nM of 60-nm liposomes in SI Appendix, Figs. S10 and S11, respectively), and at two LPS-to-phospholipid mass ratios (1:10 and 1:100), before and after the removal of the detergent using biobeads.

The data show that P. stuartii porin self-association is hindered by electrostatic repulsion between (overall negatively charged) POPS liposomes. Omp-Pst2 self-association is inhibited in the presence of rough and smooth LPSs (SI Appendix, Figs. S10 C and D and S11 C–F), additional to those already copurified with the protein (SI Appendix, Fig. S12 A and B). Omp-Pst1 self-association is not affected by inclusion of rough LPSs (which lack O-antigen but possess shorter core oligosaccharides and lipid A) in (overall neutral) POPC liposome bilayers, even at an LPS-to-phospholipid mass ratio of 1:10 (SI Appendix, Figs. S10 C and D and S11 C and D), whereas it is reduced by the inclusion of smooth LPSs (which possess O-antigen,
complete core oligosaccharides, and the lipid A) at an LPS-to-phospholipid mass ratio of 1:100 (SI Appendix, Fig. S10 I and J) and suppressed at 1:10 (SI Appendix, Fig. S11 E and F).

The data also show that detergent does not promote proteoliposome aggregation. First, removal of detergent hardly affects the size of proteoliposome aggregates when phospholipid-only
liposomes are used (SI Appendix, Fig. S10 A, B, E, and F). Second, the detergent, at concentrations much higher than used in our study, reduces the size of liposomes (SI Appendix, SI Methods and Fig. S13A), whereas incorporation of porins augments it. Additionally, smaller proteoliposome aggregates are observed when higher concentrations of liposomes are used (SI Appendix, Figs. S10 and S11 show data at 0.125 and 1.25 mg/mL), supporting the hypothesis that proteoliposome aggregation depends on the number of porins inserted per liposome (SI Appendix, Figs. S10 and S11).

We also investigated the effect of high concentrations of salt and chaotropes (urea, NH₄Cl, NaCl, and NaSCN). Efforts to investigate the effects of CaCl₂, MgCl₂, and ZnCl₂ were thwarted by the aggregating effect of these ions on liposomes. We found that Omp-Pst1–induced aggregation of phospholipid-only liposomes is reduced, albeit to different extents, in the presence of urea, NH₄Cl, NaCl, and NaSCN. In contrast, Omp-Pst2–induced aggregation of such liposomes is prevented by urea, promoted by NH₄Cl and NaCl, and unaffected by NaSCN. The presence of LPS changes these patterns, restoring self-association for Omp-Pst1 in the presence of NaCl, although still inhibiting Omp-Pst2 self-association. We note that biobeads and LPSs are incompatible, as LPSs strongly interact with both biobeads and porins, resulting in the extraction of the latter from liposome bilayers (SI Appendix, Figs. S10 C, D, I, and J and S14). Finally, we used DLS to measure the dissociation constants for lustralydimethylamino N-oxide-solubilized Omp-Pst1 and Omp-Pst2 DOTs (SI Appendix, SI Methods and Fig. S13B). Fitting of these data suggests dissociation constants of 0.6 and 0.4 μM for Omp-Pst1 and Omp-Pst2, respectively, at pH 7.

**Self-Association of Omp-Pst1 and Omp-Pst2 Is Driven by Electrostatic Interactions.** We used site-directed mutagenesis to further characterize self-association of Omp-Pst1 and Omp-Pst2 in vitro. First, we targeted the steric zipper interface observed in Omp-Pst1 DOTs (SI Appendix, Fig. S4), either by introduction of point mutations in L5 and L7 (Omp-Pst1-D213R, Omp-Pst1-N293G, and Omp-Pst1-D213R/N293R) or by deletion of the full L5–β-hairpin that supports this interface (Omp-Pst1-Δ207–216/N293G) (SI Appendix, Fig. S4D). The charge-altering mutations D213R (SI Appendix, Fig. S4E) and D213R/N293R (SI Appendix, Fig. S4F) respectively reduced and suppressed the ability of Omp-Pst1 to induce proteoliposome aggregation (Fig. 3 A and B). The L7 mutant Omp-Pst1-N293G (SI Appendix, Fig. S4C), designed to destabilize extracellular loop L5—thereby inhibiting steric zipper formation—through suppression of the two H-bonds between N293 and Tyr216, was unable to promote proteoliposome aggregation (Fig. 3 A and B and SI Appendix, Fig. S4). The inability of Omp-Pst1-N293G to induce proteoliposome aggregation was yet fully reversed by deletion of the entire L5 β-hairpin, namely, Omp-Pst1-Δ207–216/N293G (SI Appendix, Fig. S4G). Hence, the self-association properties of Omp-Pst1 are impacted by electrostatic repulsion or destabilization of the steric zipper interface, but not by the complete suppression of the L5 β-hairpin (Fig. 3 A and B). Likewise, two Omp-Pst2 mutants aimed at disrupting the 282-NLGNYG-287 steric zipper interface, namely, Omp-Pst2 N285G and Omp-Pst2-G284R/N285G (SI Appendix, Fig. S5 C and D), showed increased ability to induce proteoliposome aggregation (Fig. 3 C and D). Again, only the Omp-Pst2-G284R/N285K mutant with two positive charges added side-by-side (SI Appendix, Fig. S5E) displayed a reduced ability to induce proteoliposome aggregation, reminiscent of Omp-Pst1-Δ213R/N293R. Hence, the main driving force behind Omp-Pst1 and Omp-Pst2 self-association appears to be electrostatic attraction, while single-layered steric zipper interaction between facing monomers could underlie a sliding mechanism that regulates DOT formation. In that case, Omp-Pst1-Δ207–216/N293G should form DOTs that solely assemble through electrostatic interactions, since both steric zipper interfaces available at the surface of Omp-Pst1 should be disrupted in that mutant.

To verify this hypothesis, we crystallized Omp-Pst1-Δ207–216/N293G and solved its structure at 3.2 Å resolution (SI Appendix, Fig. S15 and Table S1). Reminiscent of type A Omp-Pst1 crystals, those of Omp-Pst1-Δ207–216/N293G belong to the C2 space group and reveal the presence of a DOT at the unit cell level (SI Appendix, Fig. S4A and B). The buried surface area per facing trimer is 1.126 Å², and the dimerization interface delineates a large negatively charged cavity characterized by a volume of 24,540 Å³.
Omp-Pst1 and Omp-Pst2 Support Cell-To-Cell Contact in *P. stuartii* Floating Communities. *P. stuartii* is highly social, forming floating communities of cells before depositing as surface-attached biofilms (12). We thus asked whether a correlation would exist between expression of *P. stuartii* porins and the formation of such floating communities. Omp-Pst1 is the major porin of *P. stuartii* (SI Appendix, Fig. S12C) and essential to its survival; hence, a knockout strategy was unsuited to challenge our hypothesis (12). Rather, we opted for an ectopic expression strategy, using as a surrogate for *P. stuartii* a strain of *E. coli* BL21 deleted of its major porins OmpF, OmpC, OmpA, and LamB: *E. coli* ΔOmp8 (22) (SI Appendix, SI Methods). Like BL21, the ΔOmp8 strain does not form detectable floating or surface-attached biofilms (SI Appendix, Fig. S16). However, this strain displays reduced growth and fitness and a longer lag-phase (SI Appendix, Fig. S17A). Ectopic expression of either Omp-Pst1 or Omp-Pst2 in ΔOmp8 cells restores normal growth and reduces the lag phase (SI Appendix, Fig. S17A). Furthermore, it confers to *E. coli* ΔOmp8 cells the ability to form floating communities similar to those formed by *P. stuartii* (Figs. 4 and 5 and SI Appendix, Fig. S16). Formation of these is independent of that of surface-attached biofilms, which recombinant ΔOmp8 strains remain unable to form (SI Appendix, Fig. S16).

We then set to verify whether mutants unable to induce aggregation of proteoliposomes would also fail at forming floating communities. ΔOmp8 cells expressing mutated versions of Omp-Pst1 (D213R, N293G, D213R/N293R, and D213R/N293K) or Omp-Pst2 (N285G, G284R/N285G, and G284R/N285K) display similar growth and lag phases as cells expressing wild-type Omp-Pst1 and Omp-Pst2, demonstrating that the mutants are well-expressed and folded, and that their diffusive properties are not affected (SI Appendix, Fig. S17 B and C). Strikingly, however, ΔOmp8 cells expressing porin mutants that are able to induce aggregation of proteoliposomes in vitro form floating communities, whereas those expressing mutants unable to self-assemble in vitro do not (Figs. 3 and 4). Thus, our data show that the expression of self-assembling *P. stuartii* porins is sufficient to enable formation of communities of cells by a non–biofilm-forming *E. coli* strain (Fig. 4 and SI Appendix, Fig. S16). We therefore propose that this mechanism is at play in the formation of *P. stuartii* floating communities (Fig. 5), wherein cell-to-cell contacts are observed. As the formation of floating communities precedes that of surface-attached biofilms (12) (Fig. 5 and SI Appendix, Fig. S18), porins could also be involved in the cell-to-cell contacts observed within the core of surface-attached biofilms (SI Appendix, Fig. S19).

**Discussion**

The crystallographic structures of Omp-Pst1 and Omp-Pst2 reveal that, within crystals, these porins are able to form DOTs through self-matching interaction of homologous segments in their extracellular loops (Figs. 1 and 2). Using liposome-based assays, we found that Omp-Pst1 and Omp-Pst2 display self-association properties in vitro (Fig. 3), while by means of ectopic expression in ΔOmp8 (a porin-devoid strain of *E. coli*), we showed that the sole expression of Omp-Pst1 or Omp-Pst2 endows these model cells with the capability to form floating communities (Fig. 4). Thus, our data suggest that the self-association of porins from adjacent cells can sustain contact between these cells. Based on buried surface area statistics, the DOTs revealed by type A crystals of Omp-Pst1 and by crystals of Omp-Pst2 and Omp-Pst1-A207-216/N293G are compatible with the adhesive properties of these porins, but the side-by-side DOTs observed in type B crystals of Omp-Pst1 are not. We thus propose that the DOT structures are the biological assemblies that contribute to rivet cells one to another in *P. stuartii* floating communities (Fig. 5), possibly in parallel with other adhesion mechanisms. Our observation that DOT formation is impared by smooth LPSs suggests that DOTs may be specific to “rough” colonies.

Floating communities of cells associated through DOTs could provide a scaffold for biofilm genesis, allowing the building of a critical biomass before deposition onto a surface and secretion of an extracellular matrix. In line with this hypothesis, cells within the core layers of *P. stuartii* surface-attached biofilms (SI Appendix, Fig. S19 A and B) display the same phenotype as those in floating communities, that is, a close contact is observed between their OMVs (Figs. 4 and 5 and SI Appendix, Fig. S19 A and B). Hence, Omp-Pst1 and Omp-Pst2 DOTs could be targeted to inhibit socialization of *P. stuartii* in its early stages—that is, before formation of a canonical biofilm, when only cell-to-cell contact is at play. We showed that a simple disruption or removal of the steroc zipper interface does not suppress the self-associating properties of the porins, but that they can be abolished in vitro and in vivo through destabilization of the steroc zipper interface or by electrostatic repulsion (Figs. 3 and 4). In yeast, steric zippers promote the selection of strains based on self-templating prions, while in amyloid diseases (19), they allow the formation of a variety of fiber polymorphs which differ in toxicity and shape. In *P. stuartii* porins, steroc zippers could serve to avoid interspecies DOT formation, thus restricting contact to cells of the same strain only.

Within crystallographic DOTs, facing channels are opened, suggesting that they could provide, in vivo, an effective conduit for the exchange of signaling solutes or nutrients by passive diffusion (Fig. 1) in the core of surface-attached biofilms (12) (Fig. 1 B and F). Also, the presence of cell-to-cell contact phenotype. It is known that within biofilms, cells exchange chemical information through a mechanism termed “quorum sensing” (QS), which orchestrates the phenotypic adaptation undergone by bacteria as they morph from the planktonic isolated state to the multicellular biofilm state (23). QS is also involved in the adaptation of biofilm cells to local environmental changes (23), in metabolic codependence (24) and time-sharing processes (25), and in the release of cells from the biofilm (23). As yet, however, it had remained unclear how soluble QS effectors could mediate intercellular communication in the first stages of biofilm formation—that is, when the cell density is low and no surrounding matrix is present. The DOT structures hint at a direct intercellular communication mechanism, which could be effective regardless of the cell density or the diffusion volume. Such a mechanism would be well adapted to enable cell cross talk in the floating communities that form before attachment on a surface. The crystallographic structures show that Omp-Pst1 forms more hermetic DOTs (virtually no fenestrations) than Omp-Pst2, suggesting that intercellular solute translocation would be more efficient across Omp-Pst1 DOTs (Fig. 1 B and F). Also, the presence of an additional constriction zone in Omp-Pst2 channel would limit large solute exchange across Omp-Pst2 DOTs (Fig. 1 J and K). Hence, Omp-Pst1 DOTs are better candidates than Omp-Pst2 DOTs for the exchange of signaling solutes (23) and nutrients (24, 25) between *P. stuartii* cells. The structure of maltose-bound Omp-Pst1 is particularly interesting in this context, because it reveals not...
only that this porin could be involved in the harvesting of maltose (and other di-glycosides) at the surface of the OM (SI Appendix, Fig. S1B), but also that the binding site for maltose is not affected by the oligomerization into a DOT. Hence, Omp-Pst1 DOTs could permit equilibration of di-glycoside concentrations between adjacent cells. In contrast, the protrusion contributed by the longer L6 loop of Omp-Pst2 would prevent the binding of a solute at this locus. Furthermore Omp-Pst2 is highly cationic selective, and the electrostatic potential developed along its channel is suggestive of a facilitated transport of cations from the periplasm to the bulk (Fig. 1F). MD simulations have revealed the propensity of Omp-Pst2 to become nonconductive when cations translocate toward the periplasm, while recent experimental work highlighted the essential role it plays in the resistance to high urea concentrations (2–5), e.g., in the urinary tract, Omp-Pst2 could facilitate the export of the ammonium that accumulates in the periplasm (12) due to P. stuartii urease activity (12). Omp-Pst2 DOTs could therefore function as check valves, allowing adjacent cells to expel cationic waste through fennescence at the dimerization interface, while not reabsorbing it. The observation that Omp-Pst2 self-association is promoted by high concentrations of ammonium chloride is in favor of this hypothesis.

In conclusion, our results suggest a previously uncharacterized role for porins, namely, to form primitive junctions between P. stuartii cells. These junctions could foster the formation of floating communities (Figs. 4 and 5) and support intercellular communications. Porin DOTs could thus represent new targets for diagnosis, disruption, and eradication of P. stuartii biofilms and associated chronic infections. It remains unclear if biofilm-forming species other than P. stuartii also form biofilms in communities before surface-attached biofilms, and, if so, whether or not porin DOTs do support the formation of these floating communities. Examination of porin structures deposited in the Protein Data Bank, and of their crystal-packing interactions, reveals that many crystallize as DOTs associated through their extracellular loops. Thus, some porins may need to be reexamined for their putative propensity to self-associate, in light of the DOTs they form in crystal structures. Further work will be needed to examine the occurrence of porin DOTs in other gram-negative biofilm-forming bacteria, and the extent to which these DOTs are supported by steric zipper interactions.

**Methods**

A full description of methods is given in SI Appendix, Materials and Methods. Briefly, E. coli strain BL21 (DE3) Δomp8 (ΔompA ompF:Ts ΔompA ΔompC) was used to generate recombinant strains. Expression of Omp-Pst1 and Omp-Pst2 in P. stuartii and E. coli Δomp8 strains was monitored using qRT-PCR. Crystalization conditions were screened using standard crystallization screens and improved manually. Porin crystals were grown by the sitting drop method, and peptide crystals by the hanging drop method. X-ray data were collected at European Synchrotron Radiation Facility (ESRF) beamlines ID14-EH4, ID23-EH2, and ID30B; processed and scaled using standard software; and phased either by molecular replacement with homology models or by direct methods. Large unilamellar liposomes were produced by the standard film hydration method and their average hydrodynamic radius was determined using DLS; epifluorescence imaging was performed using an inverted microscope. Floating and surface-attached biofilms of E. coli and P. stuartii were prepared and imaged by epifluorescence microscopy as described in ref. 12. Electron micrographs of P. stuartii floating communities were obtained by sedimentation (30 min) of fixed planktonic cells, followed by negative staining with phosphotungstic acid (5%) or sodium silicotungstic acid (SI Appendix, Fig. S19).

**ACKNOWLEDGMENTS.** We thank E. Kandiah, D. Cascio, M. R. Savaya, I. Silman, and J. Zaccar for critically reading the manuscript; C. Breydon and D. Levy for suggesting on-column delipidation of porins and sucrose gradient experiments, respectively; and A. Martel, A. Le Roy, A. Flayhan, A. Laganowski, A. Davin-Regli, E. Moiseeva, M. Zhao, G. Schoehn, and T. Vernet for stimulating discussions. We are indebted to J. Snigireva for scanning electron micrographs and J.-P. Kleman and F. Lacroix for technical support and advice during epifluorescence microscopy experiments. This work used the platforms of the Grenoble Instruct Center [Integrated Structural Biology Grenoble: Unité mixte de service 3518 CNRS–EA–UGA European Molecular Biology Laboratory (EMBL), with support from the French Infrastructure for Integrated Structural Biology (Grant ANR-10-INSB-05-02) and the Grenoble Alliance for Integrated Structural Cell Biology (GRL) (Grant ANR-10-LABX-49-01)] within the Grenoble Institute for Structural Biology. The electron microscopy facility is supported by the Rhône-Alpes Region, the Fondation de la Recherche Medicale, the Fonds Européen de Développement Régional, the CNRS, the CEA, the UGA, the EMBL, and the Groupement d’Interêt Scientifique-Infrastructures en Biologie, Santé et Agronomie. We are grateful to the ESRF for beam time under the long-term projects MX722, MX1464, and MX1583 (IBS beamtime allocation group). We acknowledge financial support from the CEA, the CNRS, the UGA, Agence Nationale de la Recherche Grant ANR-15-CE18-0005-02 (to J.-P.C.), GRAL Grant C7H-LXG1120-COLLETIER (to J.-P.C.), Laboratory of Excellence “Ion Channel Science and Therapeutics” Grant ANR-11-LABX-0015-01 (to M.V.), and Aix-Marseille University and the Service des Armées (J.-M.P.). M.E.-K. is supported by a joint CEA-GRAL doctoral fellowship (Grant C7H-LXG1120-DYNAMOP).
