Abstract—Generating complex whole-body movements for humanoid robots is now most often achieved with multi-task whole-body controllers based on quadratic programming. To perform on the real robot, such controllers often require a human expert to tune or optimize the many parameters of the controller related to the tasks and to the specific robot, which is generally reported as a tedious and time consuming procedure. This problem can be tackled by automatically optimizing some parameters such as task priorities or task trajectories, while ensuring constraints satisfaction, through simulation. However, this does not guarantee that parameters optimized in simulation will also be optimal for the real robot. As a solution, the present paper focuses on optimizing task priorities in a robust way, by looking for solutions which achieve desired tasks under a variety of conditions and perturbations. This approach, which can be referred to as domain randomization, can greatly facilitate the transfer of optimized solutions from simulation to a real robot. The proposed method is demonstrated using a simulation of the humanoid robot iCub for a whole-body stepping task.

I. INTRODUCTION

Applications involving highly redundant robots, such as humanoids, have the potential to disrupt many industries and bring countless benefits to society. Nevertheless, the design of efficient and safe controllers for humanoid platforms is highly challenging, especially for applications involving interaction with the environment. Indeed, a great number of issues can stem from the complexity of the control algorithms, task inconsistencies, or the need of guaranteeing constraints satisfaction, in order to generate physically consistent behaviors. A highly effective solution to the whole-body control problem is to decompose a complex behavior into several elementary tasks, according to a prioritization scheme \cite{1}, typically either a “strict” or a “soft” task hierarchy.

With strict prioritization strategies (such as a traditional stack-of-tasks), a fixed task hierarchy is assured by geometrical conditions such as a null space task projector \cite{2, 3}, or by the use of quadratic programming (QP) to compute optimal control actions \cite{4}. Conversely, prioritization in a soft task hierarchy (based on a weighted combination of tasks), can be achieved by assigning each task a weight defining its relative importance \cite{5, 6}.

Fig. 1: Different iCub models performing the same whole-body motion with several tasks. In this paper, with the purpose to eventually ease the passage from simulated to real-world robots, we optimize the task priorities for robustness, in order to allow their transfer from one robot model to a different one, without the need of re-tuning.

Usually, task priorities are designed \textit{a priori} by experts, then manually tuned to adjust the task ordering, timing, transitions, \textit{etc}. It is a tedious operation which, depending on the complexity of the system and the task, can take a notable portion of a researcher’s time, and can be particularly hard in the case of whole-body control of floating-base platforms.

A recent line of research seeks to tackle this issue, aiming to automatically learn whole-body task priorities \cite{7, 8, 9}. For instance in \cite{7}, task coefficients are learned for controlling a single arm, allowing the transfer of acquired knowledge to different tasks. In \cite{8}, task generalization is achieved with an evolutionary algorithm employed to learn policies for a range of tasks using parametrized motor skills. Then, in \cite{9}, task priorities guaranteeing the non violation of system constraints are learned for bimanual motions.

Learning methods often use a random exploration over numerous experiments, which could be problematic to perform on hardware. For this reason, training is preferably performed in simulation. However, inherent differences between simulated and real robots can render an optimal solution \textit{untransferable} from one to the other. This gap between reality and simulation needs to be accounted for, in order to achieve automatic parameter tuning.

Solutions to this problem have recently been addressed by trial-and-error algorithms \cite{10, 11}. In \cite{10}, prior knowledge from simulations was exploited to find acceptable behaviors on the real robot, in few trials. In \cite{11}, a trial-and-error learning algorithm encouraged exploration of the task space, allowing adaptation to inaccurate models, also in few trials.

Learning from simulation can also simplify data gathering, but there is no guarantee that the acquired knowledge is effective in the real world. For example, optimal control and
movement primitives are combined in [12] to find solutions which can be easily deployed on the real robot, but they strongly rely on the accuracy of the simulated model.

Also, since QP solvers often allow for constraints relaxation, strict constraints satisfaction is not always ensured by the frameworks presented above. In [9], the learning procedure guarantees strict constraints fulfillment, but transferring knowledge from simulation to reality did not fully achieve the desired behavior. This implies that constraints satisfaction is beneficial, but not enough to achieve transferability: solutions which are robust rather than optimal are needed, in order to achieve a better generalization.

Looking for robust solutions is central to transfer learning, which seeks to exploit previously acquired knowledge [13] to allow a model trained on one task to be re-purposed on a second related one. This approach can benefit from domain randomization (DR) [14], which consists in randomizing some aspects of the simulation to enrich the range of possible environments experienced by the learner. In [15], robust policies for pivoting a tool held in the robot’s gripper were learned in simulation, given random friction and control delays, such that the learned policies proved to be effective on the real robot as well.

This work proposes to apply the idea of DR to whole-body controllers. In this context, we want to ensure that balance is maintained while performing a task, even if large differences exist between the learning domain and the testing domain.

To achieve this result, we combine a DR approach with fitness functions promoting the robustness of the learned controller, and provide a method to learn robust task priorities which achieve desired goals, while allowing to facilitate the transfer of results from simulation to reality. The effectiveness of the proposed method is demonstrated by optimizing parameters in simulation for the goal of making the iCub effective on the real robot as well.

The robot is modelled as described in [3], where it is assumed to be a free-floating system composed of \( n + 1 \) links connected with \( n \) 1-DOF (degree of freedom) joints. The robot configuration space is characterized by \( q \), composed of the position and orientation of a base frame \( B \) attached to a link of the robot, and the joint angles \( s \). The robot velocity is expressed as \( \nu = (v_B, \dot{s}) \), where \( v_B \) is the velocity of the base frame expressed with respect to the inertial frame.

Looking for robust solutions is central to transfer learning, which seeks to exploit previously acquired knowledge [13] to allow a model trained on one task to be re-purposed on a second related one. This approach can benefit from domain randomization (DR) [14], which consists in randomizing some aspects of the simulation to enrich the range of possible environments experienced by the learner. In [15], robust policies for pivoting a tool held in the robot’s gripper were learned in simulation, given random friction and control delays, such that the learned policies proved to be effective on the real robot as well.

This work proposes to apply the idea of DR to whole-body controllers. In this context, we want to ensure that balance is maintained while performing a task, even if large differences exist between the learning domain and the testing domain.

To achieve this result, we combine a DR approach with fitness functions promoting the robustness of the learned controller, and provide a method to learn robust task priorities which achieve desired goals, while allowing to facilitate the transfer of results from simulation to reality. 1) Control input: A control input $u = [\tau^T F_c^T]^T$ is composed of joint torques $\tau$ and contact forces $F_c$, where $F_c \in \mathbb{R}^{6n_c}$ is a stacked vector of contact wrenches. Defining $J_c$ as the contact Jacobian, stacked in the same way as $F_c$, and $B = [\zeta^T J_c^T]$, the system dynamics \(^{(1)}\) can then be reformulated as

$$M(q) \ddot{q} + h = Bu$$ \hspace{1cm} (2)

2) Control objective: The developed controller has the following objectives, from which a stack of tasks is defined:
- Stabilize the center of mass position $X_{CoM} \in \mathbb{R}^3$
- Stabilize the stance foot pose $X_{stance} \in \mathbb{R}^6$
- Stabilize the swing foot pose $X_{swing} \in \mathbb{R}^6$
- Stabilize the neck orientation $X_{neck} \in \mathbb{R}^3$
- Track joint positions (postural task)
- Minimize joint torques $\tau$

The velocity $\dot{X}_T$ of a Cartesian task $T$ can be computed from the associated Jacobian $J_T$ and the robot velocity $\nu$ with $\dot{X}_T = J_T \nu$, where $T \in \{CoM, stance, swing, neck\}$. Deriving this expression yields the task acceleration:

$$\ddot{X}_T = J_T \nu + J_T \dot{\nu}$$ \hspace{1cm} (3)

In view of Eq. (2) and (3), task accelerations $\ddot{X}_T$ can be formulated as a function of the control input $u$:

$$\ddot{X}_T(u) = J_T \nu + J_T M^{-1}(Bu - h)$$ \hspace{1cm} (4)

Stabilization of a Cartesian task may then be attempted by minimizing $\ddot{X}_T(u) = \ddot{X}_T(u) - \ddot{X}_T^*$, the error on the task acceleration, where $\ddot{X}_T^*$ is a feedback term composed of reference linear accelerations obtained with a proportional-derivative (PD) feedback control policy, and reference angular accelerations computed as in [17, section 5.11.6, p.173].

As for the postural task, similarly as above, in view of Eq. (4), one can obtain $\ddot{s}(u)$, a formulation of the joint accelerations $\ddot{s}$ as a function of the control input $u$:

$$\ddot{s}(u) = \zeta^T [M^{-1}(Bu - h)]$$ \hspace{1cm} (5)

Stabilization of the postural task may then be attempted by minimizing $\ddot{s}(u) = \ddot{s}(u) - \ddot{s}^{ref}$, the error on the joint accelerations, with $\ddot{s}^{ref}$ obtained through inverse kinematics by solving the following optimization problem:

$$\ddot{s}^{ref} = \arg \min_{\ddot{s}} \frac{1}{2} \sum_T w_T |\ddot{\nu}_T|^2 + w_s |\ddot{s}|^2$$ \hspace{1cm} (6)

In the above, the error on robot acceleration is computed with $\ddot{\nu}_T = \ddot{\nu} - J_T^T (J_T \nu + \ddot{X}_T^*)$ for Cartesian tasks, and with $\ddot{s}$ a feedback term computed using a PD control policy, and $\ddot{s}^{ref}$ is a feedback term on the base velocity used to ensure convergence of the base acceleration to zero.

3) QP formulation: In the context where tasks may have relative priorities, soft task priorities would allow to achieve a trade-off between weighted tasks. A set of task weights is defined, in order to attribute each task a priority, with

$$w = \{w_{CoM}, w_{stance}, w_{swing}, w_{neck}, w_s, w_T\}$$ \hspace{1cm} (7)

The terms $w_{CoM}, w_{stance}, w_{swing}, w_{neck} \in \mathbb{R}$ refer to weights associated to the CoM, stance foot, swing foot and neck Cartesian tasks, and $w_s, w_T \in \mathbb{R}$ to the weights associated to the postural task and joint torque regularization.

The control architecture described above can thus be formulated as the following optimization problem.

$$u^* = \arg \min_{u} \frac{1}{2} \text{cost} \hspace{1cm} (8a)$$

subject to $Cu \leq b$ \hspace{1cm} (8b)

where the constraint Eq. (8b) ensures that the contact forces remain within the associated friction cones. The cost function \(^{(8a)}\) is computed as the weighted sum of all task objectives:

$$\text{cost} = \sum_T w_T \left| \ddot{X}_T(u) \right|^2 + w_s \left| \ddot{s}(u) \right|^2 + w_{\tau} |\tau(u)|^2$$

Reorganizing the terms in the cost function, one can easily verify that it has the form of a QP problem.

B. Constrained stochastic optimization

In this work, the learning problem is cast as a black-box constrained stochastic optimization. Given a fitness function $\phi(w) : \mathbb{R}^{n_p} \to \mathbb{R}$ (with $n_p$ the number of task weights to optimize), sets of $n_{IC}$ inequality constraints and $n_{EC}$ equality constraints $h, g$, the idea is to find an optimal solution $w^* \in \mathbb{R}^{n_p}$ to the problem:

$$w^* = \arg \max_{w} \phi(w)$$ \hspace{1cm} (9a)

subject to

$$g_i(w) \leq 0 \hspace{0.5cm} i = 1, \ldots, n_{IC}$$ \hspace{1cm} (9b)

$$h_i(w) = 0 \hspace{0.5cm} i = 1, \ldots, n_{EC}$$ \hspace{1cm} (9c)

The Covariance Matrix Adaptation - Evolution Strategy (CMA-ES), first described in [18], is a standard tool for solving black-box optimization problems. In its basic implementation, CMA-ES defines a multivariate Gaussian distribution $\mathcal{N}((\bar{\nu}, \sigma^2, \Sigma)$ with mean $\bar{\nu}$, step size $\sigma^2$ and covariance $\Sigma$. However, since CMA-ES was not originally designed for handling constraints, this work employs a constrained extension of it called (1+1)-CMA-ES, which uses covariance constrained adaptation (CCA) [19]. This variant was benchmarked in [9] for bimanual tasks, as well as in [20] for trajectory optimization of a whole-body movement (standing up from a chair).

A single iteration, or generation, of (1+1)-CMA-ES comprises several stages. First, a sample $w_1$ is drawn according to the rule $w_1 = w + \sigma Dz$, where $D$ is the Cholesky factor of the covariance matrix $\Sigma = D^\top D$ and $z$ is a standard normal distributed vector $z \sim \mathcal{N}(0, I)$. The fitness function $\phi$ is evaluated for this sample, and the Gaussian distribution is updated based on the result, as described in [21]. This update also exploits the previous generations to change the covariance and step size of the search distribution. Finally, information about the successful iterations is stored in a search path $s \in \mathbb{R}^{n_p}$. A more detailed description of the algorithm can be found in [20].
IV. EXPERIMENTS

This section exposes experiments with the iCub robot [22]. They were performed in order to validate empirically that the method described in section III is capable of generating task priorities which (i) produce robust whole-body motions, even when contacts due to physical interaction with the environment evolve in time, and (ii) can cope with imperfections in the model, disturbances and noise.

1) Robot setup: Experiments were conducted in simulation using the open-source robot simulator Gazebo [23]. They were performed with the iCub robot, using 23 DOF on legs, arms and torso. The robot is equipped with 6 force/torque sensors on the arms, legs and feet, allowing whole-body dynamics computations. We tested our method using two distinct models of the iCub with different inertial properties: the first one with a tethered power supply and the second one with a battery pack on the back, as shown in Fig. [1].

2) Whole-body motion: The controller described in section III-A was developed in Matlab/Simulink using WBTToolbox [24]. It can be used either for a simulated or a real robot.

It is applied to the task of performing steps, i.e. performing the following sequential movements for each step: move the CoM above the stance foot, move the swing foot up by 0.025m, move the swing foot back to its initial pose, and move the CoM back to its initial position. The passage from one movement to the next takes place when Cartesian task errors are smaller than a threshold and contact forces are consistent with the desired motion, or a maximum state duration has been reached. Over the course of a step, the desired stance foot pose, neck orientation and posture remain at their initial value.

Note that over all experiments, the proportional-derivative gains used to compute reference accelerations associated to Cartesian and postural tasks are kept constant.

The next subsections describe the experiments we performed, while Table I presents them in summary form. Training and testing were performed with different robot models and stepping tasks, as well as under different randomized conditions (RC) as described in Table II.

A. Training with the tethered iCub model

In order to optimize task weights, three different fitness functions were compared. The first one, \( \phi_p \), favored performance on the Cartesian tasks and less deployed effort. The second one, \( \phi_r \), focused on robustness, by favoring solutions with smaller excursion of the ZMP position \( P_{ZMP} \) with respect to the center of the support polygon \( O_{SP} \). The third fitness function, \( \phi_{pr} \), was a combination of the first two:

\[
\phi_p = -\frac{1}{X_{T_{\max}}} \sum_{t=0}^{t_{end}} \sum_{T} |\dot{X}_T|^2 - \frac{0.0001}{\tau_{\max}} \sum_{t=0}^{t_{end}} |\tau|^2 \quad (10a)
\]

\[
\phi_r = -\frac{1}{P_{ZMP_{\max}}} \sum_{t=0}^{t_{end}} |P_{ZMP} - O_{SP}|^2 \quad (10b)
\]

\[
\phi_{pr} = \frac{1}{2} (\phi_p + \phi_r) \quad (10c)
\]

Furthermore, \( X_{T_{\max}}, \tau_{\max} \) and \( P_{ZMP_{\max}} \) are normalization factors. Inequality constraints to the learning problem were defined on joint position limits and torque limits: they act as an extra safety built on top of the QP controller.

The task used for the optimization is to perform 1 step, as described in section IV-A. The simulation was limited to 10 seconds, allowing the robot to perform one step and shift its weight to the side in order to start a second one, making sure that the robot remained stable after foot touchdown.

Early termination of a simulation took place in cases where the robot fell or the QP in Eq. (9) could not be successfully solved (which may happen when the weights being tested are far from being optimal, and lead to a configuration in which the QP solver simply can not find a solution). In these cases, a penalty of \(-1.5\) was added to the fitness in Eq. (10).

Optimized task priorities were obtained by performing 200 iterations of (1+1)-CMA-ES [19] applied to the control framework, with an exploration rate of 0.1; each learning experiment was repeated 10 times. Since task priorities as used in Eq. (9) and (10) are relative to each other, \( w_{CoM} \) was attributed a fixed value of 1. The remaining task priorities were attributed bounds as shown in the bottom of Table II. Furthermore, the weight values \( w_0 = [1, 1, 1, 0.1, 1e-3, 1e-4] \) obtained by hand were verified to allow the tethered iCub model to successfully perform the desired stepping motion, and were therefore used as a starting point.

Moreover, to achieve robustness through domain randomization and enable the controller to eventually cope with real-world data, the robot was subjected to the randomized conditions 1 to 5 (see Table II) at each learning iteration. These conditions constitute the set of conditions \( j \) under which the controller had to perform. In particular, tests performed in simulation showed that applying a force of 10N on the chest for no more than 1 second was sufficient to destabilize the robot when using unoptimal weights. Thus, using such disturbances during learning can encourage the generation of robust task priorities.

An additional set of learning experiments was performed for \( \phi_p \) without using DR, to assess the contribution of DR.

Results showed that 200 iterations were sufficient to achieve strong convergence. Weights obtained with each of the fitness functions in Eq. (10) are shown in Table III.

B. Testing 1: with the tethered iCub model

In order to validate the robustness achieved with the optimized weights, each set of them were tested on the same iCub model used for training, but not submitted to randomized conditions. The testing task in this case was to achieve 6 consecutive steps. The success rates achieved with the optimized weights from each fitness function are shown in Table II and typical trajectories achieved using each fitness function are shown in the left part of Fig. 3 and in Fig. 4.

C. Testing 2: with the backpacked iCub model

In order to replicate conditions similar to performing experiments on the real robot, we prepared a second model of the iCub, with a battery pack installed on its back. This
The training stepwise procedure was performed in two configurations: tethered and backpacked model. Each configuration was tested on a different set of optimized weights. The results are shown in Fig. 3. As could be expected, due to the addition of noise, ZMP trajectories showed to be highly noisy and are therefore not shown. These results show that weights obtained with DR allow for a higher robustness of the controller. Additionally, the rate of success achieved with DR shows to be significantly higher than without DR, demonstrating that DR did have a measurable impact on the achieved robustness.

V. Discussion and Conclusion

In summary, the proposed method generated task priorities for successful whole-body control of different robot models, in 200 learning iterations. It was demonstrated by performing training on a first model of the iCub robot, then testing on a different model submitted to diverse working conditions.

Results achieved with $\phi_p$, a fitness function favoring task performance, were likely limited by overfitting on the model used for learning and did not allow much robustness with respect to disturbances. On the other hand, optimizing for robustness with $\phi_r$ allowed higher chances of success when changing conditions, by encouraging smaller ground reaction forces and the generation of angular momentum through contacts and other unilateral constraints. Therefore, although task priorities require proper tuning, the controller is not highly sensitive to a single precise adjustment of task weights.

Eventually, in order to further improve performance when using a different robot model or moving on to experiments on the real robot, one may be interested in performing another round of optimization on the task priorities, for example exploiting data-efficient learning methods, as done in [11].

Nonetheless, the robustness achieved with the proposed method has the potential to allow higher success when passing from simulation to real-world experiments. Further works shall explore different DR conditions, such as randomizing values associated to the dynamics of the system, control delay, or measurement noise amplitude and delay. The extension of the proposed method to additional parameters such as feedback gains will also be examined.
