(Received 22 November 2017; revised manuscript received 29 June 2018; published 11 September 2018)

A recent study of red blood cells (RBCs) in shear flow [Lanotte et al., Proc. Natl. Acad. Sci. U.S.A. 113, 13289 (2016)] has demonstrated that RBCs first tumble, then roll, transit to a rolling and tumbling stomatocyte, and finally attain polylobed shapes with increasing shear rate, when the viscosity contrast between cytosol and blood plasma is large enough. Using two different simulation techniques, we construct a state diagram of RBC shapes and dynamics in shear flow as a function of shear rate and viscosity contrast, which is also supported by microfluidic experiments. Furthermore, we illustrate the importance of RBC shear elasticity for its dynamics in flow and show that two different kinds of membrane buckling trigger the transition between subsequent RBC states.

DOI: 10.1103/PhysRevLett.121.118103

The behavior of red blood cells (RBCs) in flow has been a fascinating research topic for several decades, due to the direct biological relevance and intriguing physical mechanisms which govern the observed cell shapes and dynamics. First observations of RBCs in linear shear flow have shown that RBCs tumble (TB) or flip as a coin at low shear stresses and tank tread (TT) at high enough shear stresses [1–4]. A TT RBC adopts a nearly stationary orientation in shear flow and its membrane performs rotating motion [1,3,4]. The transition between the two motions is due to the existence of a minimum of elastic energy when the membrane is in static equilibrium, which is referred to as shape memory [5], and has been incorporated into the theoretical models for RBC dynamics [6,7]. Recently, another dynamics, RBC rolling, which appears at moderate shear stresses in between those resulting in cell TB and TT, has been discussed [8–10]. Rigidlike TB motion at low shear stresses is destabilized by a possible movement of the elastic cytoskeleton of a RBC [10] and the cell shows first a TB motion with a precession in its orientation axis, followed by the rolling motion for increasing shear stresses [10–12]. A similar behavior has been also found for oblate capsules [13,14].

Most of the mentioned studies have been performed under conditions with a low viscosity ratio $\lambda < 1$ between intracellular and extracellular fluids. This means that RBCs are suspended into highly viscous fluids in comparison to blood plasma, as $\lambda \approx 5$ under physiological conditions [15]. The use of a high-viscosity fluid medium has been driven by the limitations of experimental devices and cell tracking at high shear rates, because the high viscosity allows the application of high shear stresses at moderate shear rates. However, the viscosity ratio $\lambda$ has been shown to play a crucial role in vesicle [16–18] dynamics in shear flow, such that an increase in $\lambda$ induces the transition from vesicle TT at low $\lambda$ to TB at high $\lambda$ [16,19]. Recent simulations of RBCs in shear flow have also reported TB at large enough $\lambda$ values [20]. Other numerical investigations of RBCs [21] and oblate capsules [14] in shear flow have reported a stable rolling motion for large enough viscosity contrasts and shear rates. In contrast, a recent study [22] on blood rheology has found that RBCs at $\lambda \approx 5$ first tumble, then roll, deform into rolling stomatocytes, and finally adopt highly deformed polylobed shapes as the shear rate is gradually increased. Polylobed shapes have also been reported in early experiments on RBCs in shear flow [23] and in a theoretical study on elastic quasispherical capsules in parabolic flow [24].

In this Letter, we take a closer look at these dynamic shapes and transitions between them. In contrast, Ref. [22] was focused on the effect of these shapes on blood rheology. We construct a state diagram, which presents the observed shapes and dynamics of RBCs for a wide range of shear rates and viscosity contrasts. Then, we focus on RBC dynamics at $\lambda > 1$ and show that two of the most salient shape transitions are controlled by membrane buckling due to cell compression. These results highlight the essential role of the elastic cytoskeleton for RBC motion under physiological flow conditions.

Shapes and dynamics of RBCs are obtained from three-dimensional simulations using two different hydrodynamic techniques. The first method corresponds to a mesoscopic...
particle-based approach, smoothed dissipative particle dynamics (SDPD) [25,26], for modeling fluid flow, while a RBC membrane is represented by a triangulated network of springs [27–30] whose vertices are coupled to the fluid via frictional forces. The network assumes fixed connectivity and includes the spring’s elastic energy, bending energy, and area- and volume-conservation constraints [28,29,31]. The second simulation method relies on a finite-volume parallel solver for the incompressible Navier-Stokes equations on unstructured meshes, YALES2BIO [32,33]. Fluid-structure coupling is implemented using an immersed boundary method adapted to unstructured grids [32,34]. RBCs are discretized by a moving Lagrangian mesh and modeled as viscous drops enclosed by membranes resisting shear, bending, and area dilation [33,35]. More details on the methods can be found in the Supplemental Material [44]. Simulations are complemented by experiments of a pressure-driven flow within a slitlike rectangular channel with a 300 μm height and 3 mm width. RBCs are suspended in 4% and 2% wt/wt dextran (MW 2 × 10^6 g/mol) PBS/BSA solutions at a volume fraction of 1% at 25 °C. Local shear rates are estimated by measuring both the local cell velocity and distance from a slit wall within the range between 10 and 20 μm.

To nondimensionalize the shear rate \( \dot{\gamma} \), a characteristic RBC time \( \tau = \eta D/\mu \) is defined, where \( D = \sqrt{A/\pi} \) is an effective RBC diameter and \( A \) is the surface area, \( \mu \) is the membrane shear modulus, and \( \eta \) is the dynamic viscosity of a suspending medium. Average properties of healthy RBCs are taken to be \( A = 13.4 \times 10^{-12} \text{ m}^2 \) [36] (i.e., \( D = 6.5 \times 10^{-6} \text{ m} \)) and \( \mu = 4.8 \times 10^{-6} \text{ N/m} \). For instance, with \( \eta = 9 \times 10^{-3} \text{ Pas} \) the characteristic time is \( \tau \approx 1.2 \times 10^{-3} \text{ s} \). Membrane bending rigidity is set to \( \kappa = 70k_B T = 3 \times 10^{-19} \text{ J} \) (\( k_B \) is the Boltzmann constant and \( T \) is temperature) such that the Föppl–von Kármán number \( \alpha = \mu D^2/\kappa = 680 \) is fixed in all cases. The stress-free shape of a RBC elastic network is assumed to be an oblate spheroid with a reduced volume of 0.96. The stress-free shape of a RBC membrane affects the TB-to-TT transition [12,21,37], such that a nearly spherical stress-free shape leads to shear rates of the transition consistent with experiments [6,10], while a biconcave stress-free shape shifts the TB-to-TT transition to larger shear rates [12,21,37].

Figure 1 illustrates observed shapes in microfluidic experiments (\( \lambda \approx 8 \)) and SDPD simulations (\( \lambda \approx 5 \)) at various dimensionless shear rates \( \dot{\gamma}^* = \dot{\gamma} \tau \) (\( \tau \approx 1.2 \times 10^{-3} \text{ s} \)). The shapes are rolling discocyte, rolling stomatocyte, TB stomatocyte, trilobe, and multilobe, observed at \( \dot{\gamma}^* = 0.012, 0.18, 0.3, 0.9, \) and 2.15 in experiments and at \( \dot{\gamma}^* = 0.014, 0.18, 0.34, 0.93, \) and 3.3 in simulations, respectively. Two views, vorticity and flow-gradient directions, are shown by the arrows with unequal and equal lengths, respectively. See also movies S1–S4.

To look in more detail into the transitions between different states, we have computed RBC total energy, as shown in Fig. 3(a) for a RBC with $\lambda = 5$ from YALES2BIO simulations. As expected, the RBC total energy is a monotonically increasing function of shear rate, because the cell gets more and more deformed by the shear forces. However, we observe effective power laws with decreasing exponents as we go from one dynamic state to the other, as shown by the lines in Fig. 3(a). This implies that RBCs adopt an energetically more favorable dynamics, even though no energy minimum principles can be invoked here. Therefore, there are no simple energy arguments which could explain the existence of the shapes and transitions at specific $\dot{\gamma}^*$. 

To identify transition mechanisms between different shapes and dynamics, we monitor RBC behavior for increasing $\dot{\gamma}^*$. First, a TB-RBC in shear flow transits to a rolling discocyte at low shear rates. Here, a precession in the TB axis (i.e., the TB axis does not remain within the shear plane) is first observed, followed by a complete alignment of the RBC axis with the vorticity direction as the shear rate is increased [10–12]. This transition has been described for $\lambda < 1$ [10], and therefore, it is expected to have the same origin for $\lambda$ larger than unity. 

As the shear rate is further increased at $\lambda = 5$, a rolling discocyte transits to a rolling stomatocyte. This transition might occur due to membrane buckling, but it is difficult to observe and confirm this effect directly in shear flow. Therefore, we consider two types of cell deformation (stretching and compression), which occur in shear flow. To mimic the elongational component of the flow, a RBC is stretched (without flow) [28,33] similar to the RBC deformation by optical tweezers [39,40]. Even for very...
strong stretching deformations, a RBC maintains both of its dimples and no transition to a stomatocytelike shape occurs. Second, we place a RBC with its largest diameter of about 8 μm between two parallel walls, as shown in the insets of Fig. 3(b), and compress the cell by moving the upper wall down. When the distance between the walls becomes approximately 6.3 μm, the RBC exhibits buckling and a biconcave shape with dimples on both sides transits to a stomatocyte (see movie S5). Figure 3(b) presents the evolution of shear-elastic and bending energies, and near the buckling transition a small step in the elastic energy can be recognized. Note that the RBC buckling under compressive deformation occurs for the model with a nearly spherical stress-free shape (reduced volume of 0.96), while for a biconcave stress-free shape (reduced volume of 0.64), a RBC remains biconcave and does not transit to a stomatocyte under direct compression. Simulations of a RBC with the biconcave stress-free shape at \( \lambda = 5 \) in shear flow show no transition from the rolling discocyte to the rolling stomatocyte, in agreement with the compression simulation. Furthermore, a RBC with the biconcave stress-free shape transits from the rolling discocyte to a tumbling stomatocyte at \( \dot{\gamma}^* \approx 0.4 \) and then to a trilobe at \( \dot{\gamma}^* \approx 0.72\); these values are slightly larger than the corresponding transitions for a RBC with the near spherical stress-free shape, occurring at \( \dot{\gamma}^* \approx 0.32 \) and \( \dot{\gamma}^* \approx 0.65 \), respectively. This implies that the stress-free shape of the spectrin network of a RBC is likely to be close to a sphere, consistent with previous studies [12,21]. The transition from rolling discocyte to rolling stomatocyte for a RBC with the nearly spherical stress-free shape occurs for all considered viscosity contrasts in Fig. 2, and therefore, it should be also present at low \( \dot{\gamma}^* \). However, we observe a slight shift of this transition to higher shear rates with increasing \( \lambda \), since cell compression by shear flow at a fixed shear rate is reduced.

Following the rolling-stomatocyte state at \( \lambda = 5 \), a transition to a TB stomatocyte and then to multilobe shapes is observed for increasing \( \dot{\gamma}^* \). Hence, cell rolling becomes unstable when its deformation in shear flow becomes strong enough. Similarly, in the compression test described above [Fig. 3(b)], a stomatocytic shape becomes unstable at a certain compression when confinement between the planes is further increased (not shown).

The transition to multilobe shapes can be also achieved from TT by increasing \( \lambda \) at high shear rates (\( \dot{\gamma}^* \gtrsim 0.6 \)). Figure 4(a) shows the inclination angle and the aspect ratio of a TT RBC as a function of viscosity contrast at \( \dot{\gamma}^* = 1.36 \). As \( \lambda \) increases, both the cell’s extension and the inclination angle reduce. Approximately at \( \lambda \approx 3.2 \), a transition to multilobe shapes occurs, even though the inclination angle is still nonzero and equal to about 5°. Figure 4(b) illustrates the time evolution of RBC shapes at this transition; the membrane first forms small bumps at the top and the bottom, then very rapidly forms more lobes, and finally attains a trilobe shape (see movie S6). This is another example of a buckling transition mediated by the elasticity of the membrane, as shown in Fig. 4(c), which displays membrane’s elastic tension at four time instances with the corresponding shapes in Fig. 4(b). In particular, Fig. 4(c) demonstrates that large parts of the membrane experience negative tension in both principal directions, which is most pronounced in regions of membrane buckling. A similar appearance of local negative tension has been also reported for elastic capsules in shear flow [42]. A comparison of the inclination angle for RBCs to the Keller-Skalak (KS) theory for fluid vesicles [41] using cell dimensions measured in simulations. (b) Time evolution (\( t^* = \dot{\gamma}^* t \)) of shapes at \( \lambda = 3.5 \) (starting from a simulation with \( \lambda = 3.1 \)), when TT becomes unstable and a trilobe is formed (see movie S6). (c) Membrane’s elastic tension in the direction of the smallest (top) and largest (bottom) local strains.

FIG. 4. Trilobe formation. (a) Inclination angle (square and plus symbols, left axis) and aspect ratio (maximum to minimum size, red bullets, right axis) of a RBC as a function of \( \lambda \) at \( \dot{\gamma}^* = 1.36 \) from YALES2BIO simulations. The square and bullet symbols correspond to simulation measurements, while the plus symbols are obtained from the Keller-Skalak theory for fluid vesicles [41] using cell dimensions measured in simulations. (b) Time evolution (\( t^* = \dot{\gamma}^* t \)) of shapes at \( \lambda = 3.5 \) (starting from a simulation with \( \lambda = 3.1 \)), when TT becomes unstable and a trilobe is formed (see movie S6). (c) Membrane’s elastic tension in the direction of the smallest (top) and largest (bottom) local strains.
Affect the TT frequency of RBC membrane [28, 43], where a simulations. For instance, membrane viscosity is known to ratios. In particular, physiological conditions of presented for a wide range of shear rates and viscosity rotating trilobe) in shear flow.

RBC mainly performs rotational motion (i.e., TB, rolling, here is that most observed shapes (except TT) do no exhibit explanation for a secondary role of membrane viscosity shearing motion of the membrane occurs. A plausible diagram in Fig. 2, since it was not considered in the membrane is of secondary importance for the RBC shape experiments suggests that the viscosity of a RBC mem-
bware buckling due to RBC compression in flow drives the transition between rolling discocytes and stomatocytes and determines the appearance of multilobar shapes at large λ and $\dot{\gamma}$. Interestingly, for a RBC with the nearly spherical stress-free shape, membrane buckling occurs at lower shear stresses than for a RBC with the biconcave stress-free shape. This supports the idea that the stress-free shape is indeed spheroidal. The buckling mechanism for the shape transitions highlights the importance of RBC shear elasticity and stress-free shape for its dynamics in flow.

In summary, a diagram of RBC shapes and dynamics is presented for a wide range of shear rates and viscosity ratios. In particular, physiological conditions of $\lambda \approx 5$ are thoroughly investigated. Furthermore, we show that membrane buckling due to RBC compression in flow drives the transition between rolling discocytes and stomatocytes and determines the appearance of multilobar shapes at large $\lambda$ and $\dot{\gamma}$. A good qualitative agreement between simulations and experiments suggests that the viscosity of a RBC membrane is of secondary importance for the RBC shape diagram in Fig. 2, since it was not considered in the simulations. For instance, membrane viscosity is known to affect the TT frequency of RBC membrane [28, 43], where a shearing motion of the membrane occurs. A plausible explanation for a secondary role of membrane viscosity here is that most observed shapes (except TT) do not exhibit a significant in-plane shearing of the membrane, such that a RBC mainly performs rotational motion (i.e., TB, rolling, rotating trilobe) in shear flow.

In summary, a diagram of RBC shapes and dynamics is presented for a wide range of shear rates and viscosity ratios. In particular, physiological conditions of $\lambda \approx 5$ are thoroughly investigated. Furthermore, we show that membrane buckling due to RBC compression in flow drives the transition between rolling discocytes and stomatocytes and determines the appearance of multilobar shapes at large $\lambda$ and $\dot{\gamma}$. Interestingly, for a RBC with the nearly spherical stress-free shape, membrane buckling occurs at lower shear stresses than for a RBC with the biconcave stress-free shape. This supports the idea that the stress-free shape is indeed spheroidal. The buckling mechanism for the shape transitions highlights the importance of RBC shear elasticity and stress-free shape for its dynamics in flow.
