ABSTRACT

Autophagy is an ubiquitous mechanism involved in the lysosomal-mediated degradation of cellular components when engulfed in vacuoles called autophagosomes. Autophagy is also recognized as an important regulator of the innate and adaptive immune responses against numerous pathogens, which have, therefore, developed strategies to block or use the autophagy machinery to their own benefit.

Upon Human Immunodeficiency Virus-1 (HIV-1) infection, viral envelope glycoproteins (Env) induce autophagy-dependent apoptosis of uninfected bystander CD4\(^+\) T lymphocytes, a mechanism likely contributing to the loss of CD4\(^+\) T cells. In contrast, in productively infected CD4\(^+\) T cells, HIV-1 is able to block Env-induced autophagy in order to avoid its antiviral effect. To date, nothing is known about how autophagy restricts HIV-1 infection in CD4\(^+\) T lymphocytes. Here we report that autophagy selectively degrades the HIV-1 transactivator Tat, a protein essential for viral transcription and virion production. We demonstrated that this selective autophagy-mediated degradation of Tat relies on its ubiquitin-independent interaction with the p62/SQSTM1 adaptor. Taken together, our results provide evidence that the anti-HIV effect of autophagy is specifically due to the degradation of the viral transactivator Tat, but this process is rapidly counteracted by the virus to favor its replication and spread.

IMPORTANCE

Autophagy is recognized as one of the most ancient and conserved mechanism of cellular defense against invading pathogens. Crosstalks between HIV-1 and autophagy have been demonstrated depending on the virally challenged cell type, and HIV-1 has evolved strategies to block this process to replicate efficiently. However, the mechanisms by which
autophagy restricts HIV-1 infection remain to be elucidated. Here, we report that the HIV-1 transactivator Tat, a protein essential for viral replication, is specifically degraded by autophagy in CD4+ T lymphocytes. Both Tat present in infected cells and incoming Tat secreted from infected cells are targeted for autophagy degradation through an ubiquitin-independent interaction with the autophagy receptor p62/SQSTM1. This study is the first to demonstrate that selective autophagy can be an anti-viral process by degrading a viral transactivator. In addition, the results could help in the design of new therapies against HIV-1 by specifically targeting this mechanism.

INTRODUCTION

Macroautophagy, herein referred to as autophagy, is a major cellular catabolic pathway highly regulated in eukaryotes. It is involved in the degradation of cytoplasmic material after its sequestration in vacuoles called autophagosomes. The autophagosomes fuse with lysosomes to form autolysosomes in which the sequestered material is degraded and then recycled (1). Since the discovery of the Atg genes that regulate this process, autophagy has been involved in a number of important cellular functions including cellular homeostasis, development, aging or innate and adaptive immune responses (2, 3). Autophagy is believed to be one of the most ancient defense processes against invading pathogens. Its antiviral effect has been described in many studies through different mechanisms including a direct degradation of cytoplasmic viral components as for example shown for the Sindbis virus (SIN) capsids that are specifically targeted to autophagy upon interaction with p62 (4, 5). Importantly, pathogens have evolved different means to inhibit or use autophagy to their own profit (6).
At the molecular level, two signaling complexes are involved in the induction, the elongation and the closure steps of autophagy, leading to the formation of autophagosomes. Briefly, the class III PI3Kinase, associated with p150 and Beclin 1, is responsible for the formation of the phagophore. Two ubiquitination-related conjugation systems, leading to the formation of the Atg12–Atg5–Atg16L complex and the Atg8-Phosphatidylethanolamine (PE) complex, are required for the elongation and closure of the autophagosome. These two conjugates are formed upon the action of a unique E1-activating enzyme called Atg7. ATG8-PE is inserted in the autophagic vacuole membranes and is present all along the pathway, a characteristic that makes it an autophagosomal marker. As autophagy proceeds, ATG8-PE is finally degraded in autolysosomes. Six orthologs of ATG8 exist in mammals, three microtubule-associated protein 1 light chain 3 (LC3) proteins (LC3A, B, and C), one gamma-aminobutyrate receptor-associated protein (GABARAP) and two GABARAP-like proteins (GABARAPL1 and GATE16/GABARAPL2). All these proteins are synthesized as precursors that are rapidly processed at their C-terminus, leading to the exposure of a glycine residue that can be conjugated to PE (7-9). LC3B is still the most extensively studied ATG8 protein and will be hereafter referred to as LC3.

Autophagy can be a very selective process by the action of adaptor proteins behaving as autophagy cargo receptors, themselves degraded by autophagy due to their interaction with LC3 (10). Autophagy cargo receptors share at least one domain, the LIR domain (LC3-Interacting Region), allowing interaction with ATG8 family members and thus targeting the cargos to autophagosomes (11). p62/SQSTM1 (sequestosome 1, hereafter called p62) is a typical autophagy receptor that interacts with ubiquitinated substrates via its UBA domain (UBiquitin Associated domain) and that is able to multimerize via its PB1 domain (NH2-terminal Phox and Bem1p domain). These two motifs are important for selective autophagic
degradation of ubiquitinated substrates (10, 12-14). Of note, p62 has been involved in the lysosomal-mediated degradation of incoming pathogens, a process termed “xenophagy” (15, 16).

Type 1 Human Immunodeficiency Virus (HIV-1) infects immune cells, mainly CD4+ T lymphocytes and macrophages. In most instances, viral entry is mediated by the interaction of the viral envelope glycoproteins (gp120 and gp41, called Env) with CD4 and a co-receptor, mainly CCR5 or CXCR4, expressed at the surface of the target cells, to initiate a membrane fusion event. The gp120 interacts first with CD4, triggering conformational changes leading to increased exposure of gp120 regions able to bind to the co-receptor. This interaction induces a structural rearrangement in gp41 and the insertion of its N-terminus fusion peptide into the target cell membrane, leading to the fusion between viral and cell membranes and thus to viral entry (17). The RNA viral genome is then retro-transcribed in DNA by the viral reverse transcriptase and is transported to the nucleus where it integrates the genome of the host cell by the action of the viral integrase. After the integration step, the viral transactivator Tat enables the transcription of the viral DNA, leading to the production of the viral components necessary to synthesize new infectious particles that are released from the infected cells. The HIV-1 replication cycle can thus be divided in two phases: the early phase, from viral entry to provirus integration, and the late phase, from transcription of viral genes to the release of new viral particles (18, 19).

Tat is a small HIV-1 protein of 80 to 103 amino acids, depending on the viral strain, necessary for the transcription of all the viral genes after its binding to the TAR RNA loop present in the HIV-1 Long Terminal Repeat (LTR) promoter (20). In addition to its role in infected cells, Tat can be secreted and captured by bystander cells where it can induce apoptosis or modulate the expression of cellular proteins, in particular pro-inflammatory cytokines (21-24).
Complex links exist between HIV-1 and autophagy, depending on the cell types and on the infectious status of the target cell type, i.e. if the target cell is productively infected or not (25-27). In dendritic cells, HIV-1 is able to block autophagy, impeding viral antigen presentation (28, 29). In CD4⁺ T lymphocytes, we previously demonstrated that autophagy is induced by the gp41 fusogenic function and that this process leads to apoptosis of uninfected bystander CD4⁺ T cells, i.e. cells that have been in contact with infected cells without being productively infected (30, 31). In contrast, autophagy is blocked in productively infected CD4⁺ T cells (32).

In macrophages that have been challenged by the virus but not productively infected, autophagy is inhibited via the activation of Stat3 and Src-Akt by Tat and IL10 (33). HIV-1 Tat also suppresses STAT1 activation triggered by IFNγ in monocytes and IFNγ-induced autophagy in primary macrophages, suggesting that inhibition of autophagy could impair the immune defenses by blocking the antigen processing required for the recognition and killing of intracellular pathogens (34). These results are consistent with the fact that macrophages do not undergo Env-mediated apoptosis and are not subjected to depletion during HIV-1 infection.

The mechanism by which autophagy exerts its restriction activity against HIV-1 infection in CD4⁺ T cells remains to be fully characterized. We demonstrate here that p62 interacts with Tat and targets it to lysosomal-mediated degradation via selective autophagy. This interaction is not mediated by a conventional domain of p62 since the UBA or the PB1 domains of this protein are not involved. Interestingly, both neo-synthesized Tat in infected cells and exogenous Tat internalized by uninfected cells are sensitive to autophagic degradation, indicating that all the functions of Tat could be counteracted by autophagy. In conclusion, we propose that degradation of the viral transactivator Tat by selective
autophagy is a not yet appreciated potent antiviral cellular mechanism against HIV-1
infection of CD4+ T lymphocytes.

**MATERIALS AND METHODS**

**Ethics statement.** Primary CD4+ T cells were purified from blood obtained from the EFS
(Etablissement Français du Sang). Procedures using human cells were approved by the
Human Experimentation and Ethics Committee of the CNRS Institute. The HIV-1 infection
experiments were performed in a Biological Safety Level 3 laboratory. Cell culture was
performed in a Biological Safety Level 2 laboratory.

**Cell culture.** The original HEK.293T cell line, HEK expressing wild type CD4 and wild type
CXCR4 and HEK stably expressing Env at their surface were cultured in DMEM supplemented
with antibiotics and 10% fetal calf serum (FCS). MAGIC5B cells (cell line expressing CXCR4
and CCR5 and the β-galactosidase under control of the HIV long terminal repeat (LTR) were
obtained from T. Masashi (Tokyo, Japan) and cultured in DMEM supplemented with
antibiotics and 10% FCS. MOLT cells are non-adherent human acute lymphoblastic leukemia
cells. The chronically HIV-1-infected MOLT cells (MOLT-X4) and the uninfected parental cell
line (MOLT) were provided by J. Blanco (Barcelona, Spain). The 8.E5 cell line is a CEM-derived
T-cell line containing a single integrated copy of HIV-1 and unable to produce infectious
virions. T cell lines were cultured in RPMI 1640 medium supplemented with antibiotics and
10% FCS. Primary CD4+ T cells were isolated from Peripheral blood mononuclear cells and
purified by negative selection using the CD4+ Rosette separation technique (Stem Cell
Technologies). Cells were phenotypically analyzed, stimulated with 2 μg of
phytohemagglutinin (PHA) for 24h and maintained in culture by adding 100 U/ml of interleukin 2 (IL-2) (Boehringer Mannheim) every 2-3 days.

**Reagents and antibodies.** Torin 1 (To) was purchased from Tocris, 3-methyladenine (3-MA), PHA, E64d and Pepstatin A (AP) were purchased from Sigma-Aldrich. T20 was obtained from the NIH AIDS Reagent Program. Anti-LC3 (ref. L7543), anti-GAPDH (reference G9545), anti-ATG7 (ref. A2856) and anti-FLAG-HRP (ref. A8592) were obtained from Sigma-Aldrich, anti-Tat (ref. sc65912) and anti-Beclin 1 (ref. sc11427) were purchased from Santa-Cruz Biotechnologies. The monoclonal anti-p24 antibody (Ab) was from the NIH AIDS Reagent program.

**Plasmids.** The pNL4-3 molecular clone has been obtained from the NIH AIDS Reagent Program. The different p62 constructs, cloned in a pENTR plasmid, were a kind gift from Dr Terje Johansen (University of Tromsø, Tromsø, Norway). After a LR clonase reaction, we have cloned the different p62 cDNA in pDEST vectors in order to obtain GST-fused proteins, using the Gateway® Cloning Technology (Life Technologies). The LC3B cDNA was first cloned in a pENTR vector and then cloned in a pDEST vector using the Gateway® Cloning Technology (Life Technologies). The GST-LC3F52A mutant was obtained by mutagenesis using the Quickchange kit from Stratagene. The FLAG-tagged Tat (86 residues; BH10 isolate) has been cloned in the pBi-GL expression vector under the control of a tetracyclin response element (TRE) (The FLAG is placed at the C-terminal part of Tat). To express the gene of interest, the plasmid needs to be co-transfected with a pUHD-neo vector responsible for the expression of the tTA regulatory proteins needed to transactivate the TRE. The pBi-Tat K50-51A mutant, expressing the FLAG-TatK50-51A mutant, was generated from the pBi-Tat using the
Quickchange kit from Stratagene (35). The FLAG-Tat K71R expression vector was a kind gift from Monsef Benkirane (as for pBi-GL-Tat, the FLAG tag is located at the C-terminus of Tat) (36).

The different constructs expressing Vif, Nef and Vpr were cloned in a pENTR plasmid and transferred in a pCI-neo3xFLAG expression vector after a LR clonase reaction using the Gateway® Cloning Technology (Life Technologies). The expression vector coding for GFP-LC3 was kindly provided by T. Yoshimori (Osaka University, Japan) and R. Willey (NIAID, NIH). The expression vector coding for Gag was kindly provided by Nathalie Chazal (CPBS, Montpellier) (37).

**TEM analysis.** Cells were fixed *in situ* with 2.5% glutaraldehyde in cacodylate buffer (pH 7.4) for 60 min at 4°C, post-fixed with 2% osmium tetroxide, then washed in cacodylate buffer containing 0.5% tannic acid. After extensive washes in 0.1 M Sorensen phosphate buffer (pH 7.2), cells were included in a fibrin clot as described by Charret and Fauré-Fremiet (38). Cells were then post-fixed with 2% osmium tetroxide and 0.5% tannic acid, dehydrated, and embedded in epon (Embed-812, Electron Microscopy Sciences Inc.). Sections were counterstained with uranyl acetate and lead citrate and examined with a Hitachi H7100 TEM.

**HIV-1 infection and production.** To produce HIV virions, HEK cells were transfected with pNL4-3 and supernatants were collected 2 days post-transfection. Viral particles were concentrated by ultracentrifugation. Jurkat cells were then challenged for 24h with dilutions of the concentrated viruses. Flow cytometry analysis of Gag⁺ cells was performed in order to
quantify the multiplicity of infection (MOI). Quantification of the viral particles production was performed with a p24 Enzyme-linked immunosorbent assay from “Innogenetics” (Innotest® HIV antigen mAb) according to the manufacturer’s instructions. CD4+ T cells were infected with concentrated viruses at a MOI comprised between 0.1 and 1. Co-culture experiments were done with chronically HIV-infected (MOLT-X4) or uninfected T cells (MOLT) co-incubated for indicated times with HEK/CD4/CXCR4 or MAGIC5B cells.

Quantification of HIV infection of target cells was measured by flow cytometry (for HEK cells) or β-galactosidase activity assay (for MAGIC5B cells).

**GST pull-down experiments.** Constructs expressing GST proteins fused to wild type LC3 (GST-LC3), mutated LC3 (GST-LC3 F52A), wild type p62 (GST-p62) or mutated p62 (GST-p62 ΔLIR, GST-p62 ΔUBA and GST-p62 ΔPB1) were co-transfected in HEK cells with the pBi- FLAG -Tat and pUHD vectors. Corresponding empty vectors were used as controls. Anti-proteases (E64d + Pepstatin A) were added to the transfected cells in order to optimize the expression of Tat. Cell lysis was performed 24h post-transfection in 150 mM NaCl, 20 mM Tris pH 7 and 0.5% NP40 at 4°C. After centrifugation for 20 min at 4°C, the lysates were incubated with glutathione-conjugated sepharose beads for 2h at 4°C. Unbound proteins were removed by 4 washes with cold lysis buffer. Bound proteins were then eluted by boiling for 10 min in Laemmli buffer and separated by gel electrophoresis followed by immunoblotting with specific antibodies.

**Flow cytometry**
The percentage of HIV-1-infected cells was determined by quantifying the cellular levels of p24\textsuperscript{gag} by flow cytometry using the HIV KC57 FITC kit according to the manufacturer's instructions (Beckman Coulter). Briefly, cells are fixed, permealized and the anti-p24 antibody is added to the cells. After staining for 30 minutes, cells were washed with PBS, and fluorescence intensity was measured on a COULTER EPICS XL Flow Cytometer (Beckman Coulter).

**β-galactosidase assay.** Chemiluminescent reporter assay system “Galacto-Star™ β-Galactosidase Reporter Gene Assay System for Mammalian Cells”, from Life Technologies, was used to quantitate β-galactosidase activity according to manufacturer’s instruction. Briefly, 0.5x10\textsuperscript{6} MAGICSB cells were lysed in 200µl of lysis buffer provided by the manufacturer. 50µl of cell lysate was used in each assay, in duplicates. The results were normalized by quantifying the total protein concentrations using the Bradford assay from Sigma-Aldrich.

**Transfections.** 0.5x10\textsuperscript{6} HEK or HEK/CD4/CXCR4 cells were cultured in 6-well plates 24h prior to transfection. Plasmids were then transfected using the TurboFect reagent (Fermentas) according to the manufacturer’s instructions. Smartpool p62 siRNA and control siRNA were from ABgene. Beclin 1 siRNA and Atg7 siRNA were synthetized and annealed by Eurogentec. The mRNA sequences to be targeted for Beclin 1 and Atg7 siRNA were 5’- CAGUUUGGCACAAUCAAUA-3’ and 5’-GCAUCAUCUUCGAAGUGAA-3’, respectively. Transfection of siRNA into HEK/CD4/CXCR4 or MAGICSB cells (0.5.10\textsuperscript{6} cells maintained in 6-well plates) was performed with the LipoRNAiMax reagent (Invitrogen) according to the
manufacturer’s instructions. In the case of siRNA and plasmid co-transfections, 0.25x10⁶ HEK cells were first transfected with siRNA using the LipoRNAiMax reagent and, 24h later, siRNA-transfected cells were transfected with the plasmid using the TurboFect reagent.

**Western blot.** Cell lysates were loaded in a 12% Prosieve™ 50 gels (Lonza) and transferred to PVDF membranes. After a blocking step for 1h at room temperature in PBS containing 0.5% casein, membranes were incubated overnight at 4°C with the primary antibody (Ab) in the blocking buffer. After 3 washes with PBS supplemented with 0.05% Tween, the membranes were incubated for 1h at room temperature with peroxidase-coupled secondary Ab. Upon extensive washes, membranes were incubated with the Luminata Western HRP Substrate (Millipore). Proteins were detected by chemiluminescence and imaged with a G-box camera (Syngene imaging system). The expression level of GAPDH was used as loading control in all the western blots and for quantification. Quantification of protein expression was done with the Genesys software (Syngene).

The LC3-conjugated form to PE, named LC3-II, presents a higher electrophoretic mobility in gels and was, therefore, used to quantify autophagy.

**Fluorescence analysis of autophagy.** HEK/CD4/CXCR4 cells were cultured in six-well plates and transfected with pEGFP-LC3 using the TurboFect reagent (Fermentas) according to the manufacturer’s instructions. Transfected cells were then left to adhere on coverslips before co-culture with MOLT cells (negative control) or chronically infected cells (MOLT-X4) for indicated times (from 2h to 48h). Human primary CD4⁺ T cells were transfected with pEGFP-LC3 using the Nucleofector apparatus (Amaxa Biosystems) according to the manufacturer’s instructions. Transfected primary T cells were then co-cultured on coverslips for 4h with
effector cells expressing or not the viral envelope at their surface (HEK.Env or HEK, respectively). Coverslips were washed with PBS and cells were fixed in a 3.7% paraformaldehyde/PBS solution for 10 min at room temperature and analysed by epifluorescence using a Leica microscope. Autophagic cells were defined as cells containing at least 5 GFP-LC3 puncta. More than 100 transfected cells were analysed by two different investigators. Results are from at least three independent experiments.

Statistics. Analysis of the variance of the results was performed after arc sine transformation of the data when percentages were compared (39). Differences were considered significant at *p < 0.05, **p < 0.01, and ***p < 0.001.

RESULTS

Induction of autophagy decreases viral production in HIV-1-infected CD4⁺ T lymphocytes. We, and others, have previously showed that autophagy is blocked in productively HIV-1-infected CD4⁺ T lymphocytes, suggesting that autophagy is an anti-HIV process counteracted by this virus (32, 40). To examine this hypothesis, activated primary CD4⁺ T cells were infected by HIV-1 for 3 days (~20% infection). Then, autophagy was induced by adding Torin 1, an inhibitor of the mTOR kinase, for 24h. The level of viral particle production was measured by quantifying the viral capsid protein p24 by ELISA. As expected, we detected a significant decrease of HIV-1 p24 levels in the supernatants of cells treated by Torin 1 (Fig. 1A). The same results were obtained when Torin 1 was added to infected Jurkat cells (Fig. 1B) or chronically infected CD4⁺ T cells (MOLT-X4) (Fig. 1C). Thus, addition of Torin 1 decreases viral production, supporting the anti-HIV role of autophagy.
Tat interacts with p62 and is specifically degraded by Torin 1-induced autophagy. We performed a two-hybrid screen to analyze the interactions between several HIV-1 proteins (Tat, Vif, Vpr and Nef) and a bank of ATG proteins. Among the viral proteins tested, the transactivator Tat was the only viral protein able to bind p62 (data not shown), highly suggesting a role for selective autophagy. This interaction was further confirmed in vitro using a GST pull down assay in which Tat was found to interact with GST-p62 but not GST alone (Fig. 2A). As p62 is an autophagy receptor involved in the specific degradation of proteins or organelles by autophagy, we then analyzed whether induction of autophagy could affect the expression level of Tat. To this aim, we transfected human embryonic kidney (HEK) cells with a plasmid expressing a FLAG-Tat construct and autophagy was induced upon addition of Torin 1 for 3h. We observed a significant decrease in Tat levels upon Torin 1 treatment (Fig. 2B). Importantly, this effect was reversed in cells pre-treated with a cocktail of anti-proteases (E64d + Pepstatin A, AP) previously described to block lysosomal-mediated degradation (Fig. 2B). Furthermore, inhibition of lysosomal proteases, in absence of autophagy induction, showed increased levels of Tat expression in cells, suggesting that the viral transactivator can be degraded by lysosomes (Fig. 2B and 2D). The levels of the ectopically expressed viral proteins Gag, Vif or Nef was not affected by the addition of Torin 1 (Fig. 2C). These data strongly suggest that the Torin 1-induced decrease of Tat level is selective and rely on an autophagy-dependent lysosomal-mediated degradation. The results were confirmed in a context of viral infection using a HIV-1 chronically infected T cells (MOLT-X4 cells) which constitutively produce the viral Tat protein. As shown in figure 2D, Tat levels were also decreased in MOLT-X4 cells upon Torin 1 treatment for 3h, and the autophagy-inducing drug effect could be reversed by AP treatment. Since Tat is essential for
HIV-1 replication cycle, these results extend further those presented in figure 1 in which drug-mediated induction of autophagy strongly decreased viral release.

To confirm that the autophagic process is responsible for the lysosomal-mediated degradation of Tat, we down-regulated the expression of the essential autophagy-related protein ATG7 using siRNA. As shown in figure 2E, while the control siRNA did not prevent Torin-1-induced Tat degradation, the viral transactivator expression levels were significantly increased in cells for which ATG7 expression was reduced. Outstandingly, even if siRNA-mediated ATG7 decreased expression was of 30% only, Tat levels became totally insensitive to Torin 1 treatment, confirming the contribution of the autophagy pathway in Tat degradation. This result also indicates that this process is finely tuned and relies on a fully functional autophagy process.

Since we observed that Tat was interacting with p62 (see Fig. 2A), we aimed at analyzing Tat levels when p62 expression was decreased. Remarkably, we noted that the siRNA-mediated decrease of p62 expression correlated with a significant increase in Tat protein signal compared to levels obtained in lysates from siCT-treated cells (Fig. 2F). Overall, these results demonstrated that the autophagy pathway significantly contributes to Tat degradation and the autophagy receptor p62, shown to interact with Tat, could confer selectivity in this process.

The interaction between Tat and p62 is ubiquitin-independent. As we demonstrated that Tat interacts with p62 and since p62 is known to induce the selective autophagic degradation of substrates by interacting with LC3, we further analyzed whether Tat could be present in complexes with LC3. We thus performed GST pull-down experiments after co-transfection of plasmids expressing GST-LC3 and FLAG-Tat in HEK cells. As shown in figure
3A, Tat co-precipitates with GST-LC3. To assess whether this interaction was p62-dependent, we co-transfected cells with constructs expressing FLAG-Tat and a GST-tagged mutant of LC3 unable to interact with p62 (GST-LC3F52A) (36, 41). We observed that Tat did not co-precipitate with LC3F52A (Fig. 3A), indicating that the interaction between Tat and LC3 was indirect and seemingly regulated by p62. To confirm this hypothesis, we tested the interaction between Tat and a mutated form of p62 that does not interact with LC3 (GST-p62ΔLIR). As expected, this mutant still interacted with Tat hence with an apparently increased efficacy, which could be explained by the lack of targeting to autophagy-mediated degradation and thus a prolonged protein complex stability (Fig. 3A, lane 6).

The autophagy receptor p62 has been reported to selectively address ubiquitinated proteins or ubiquitinated organelles to autophagic degradation via specific recognition of ubiquitin moieties through its UBA domain, and the PB1 domain contributes to this process. We thus analyzed the interaction between Tat and mutated forms of p62 for which the UBA (GST-p62ΔUBA) or the PB1 (GST-p62ΔPB1) domains were deleted. As shown in figure 3B (lanes 3 and 4), Tat still interacted with these two p62 mutants, indicating that ubiquitination might not influence the interaction between p62 and Tat in vitro. In accordance with this result, Tat mutants on known ubiquitinated lysines, previously reported to regulate Tat activity and stability (K71 and K50-51, respectively) (36, 42, 43) are still degraded upon induction of autophagy by Torin 1 (Figure 3C).

**Autophagy is induced by HIV-1 envelope glycoproteins (Env) at the very first steps of HIV-1 infection.** To further decipher whether Tat degradation by autophagy could be relevant in vivo, we analyzed its occurrence in the context of HIV-1 infection. Indeed, we already demonstrated that autophagy is induced in uninfected bystander CD4+ T lymphocytes after
48h of co-culture with Env-expressing cells (31). We extended this finding with experiments showing that the fusogenic function of gp41 is responsible for the observed Env-induced autophagy (30). Given that the gp41-mediated fusion process is an early HIV-1 entry event, we investigated whether autophagy could be induced very rapidly after contact of Env with its receptors on target cells, before productive infection. To this aim, HEK cells expressing HIV receptors (HEK/CD4/CXCR4) and transfected with a plasmid expressing GFP-LC3, were co-cultured with chronically infected T cells (MOLT-X4), or uninfected T cells (MOLT) as a negative control. The level of autophagy and the percentage of infected cells were analyzed at different time points of co-culture. As shown in figure 4A, autophagy was rapidly induced in read-out cells upon co-culture with MOLT-X4, with a peak around 4h corresponding to the early phase of HIV-1 infection (19). Autophagy was then negatively regulated and finally completely inhibited after 24h of co-culture, a step corresponding to the late phases of HIV-1 infection. Importantly, induction of autophagy is inversely correlated with the level of infection. Of note, the same pattern was obtained when GFP-LC3 transfected cells were challenged with cell free HIV-1 (data not shown). We next analyzed whether the viral envelope was contributing to this early autophagy induction during early events of HIV-1 infection of CD4+ T cells. Primary CD4+ T cells, expressing GFP-LC3, were co-cultured with effector cells stably expressing Env, or not, at their surface (HEK.Env and HEK cells, respectively). As shown in figure 4B, Env alone was able to rapidly and significantly induce autophagy in target cells. To confirm and reinforce these data, we took advantage of another autophagy read-out by analyzing the phenotype of primary CD4+ T cells by transmission electron microscopy upon 4h of co-culture with HEK cells stably expressing Env or not. We detected the appearance of numerous autophagic vacuoles in the cytoplasm of target CD4+ T cells only in the presence of Env (Fig. 4C). Thus, Env is able to induce
autophagy in target cells upon early contact with infected cells. It is interesting to note that, as shown for Env-mediated autophagy in longer kinetics of co-culture (30), this early autophagy induction was dependent on the gp41 fusogenic function. Indeed, the addition of T20 to the co-culture, a gp41-mediated fusion peptide inhibitor, completely abolished the Env-induced autophagy (Figure 4D).

We then analyzed whether later steps of autophagy could be induced or blocked when cellular lysosomal proteases were inhibited by AP. As evidenced in figure 4E, the increased level of LC3-II obtained upon 4h of contact with Env-expressing HEK cells was further enhanced in lysates from cells also pre-treated with AP, confirming that the induced autophagy flux was not blocked during the early time points of contact between the viral envelope and CD4+ T cells.

To confirm that Tat could be a selective target for autophagic degradation in the context of productive infection, we analyzed its expression levels upon Env-induced autophagy during HIV-1 infection. For this purpose, we transfected a plasmid expressing FLAG-Tat in HEK/CD4/CXCR4 and co-cultured these cells with MOLT-X4 during 4h, a time previously shown to correspond to the peak of Env-mediated autophagy induction, or 48h, a time for which autophagy was seemingly inhibited (Fig. 4A). As expected, the level of LC3-II was increased up to 70% after 4h of co-culture while being decreased by 40% upon 48h of co-culture with MOLT-X4 cells, strongly supporting an early induction of autophagy followed by its blockade during HIV-1 infection. Remarkably, Tat expression levels were inversely correlated to those of LC3-II, meaning that Tat is depleted when autophagy is induced while this effect was not observed under conditions where autophagy is inhibited by the virus (Fig. 4F).
Env-induced autophagy triggers Tat degradation and consequently represses HIV-1 LTR activation. In order to assess the contribution of Env-mediated autophagy induction in Tat degradation, we transfected a plasmid expressing FLAG-Tat in HEK/CD4/CXCR4 and treated these cells with the autophagy initiation inhibitor 3-methyladenine (3-MA) before co-culture for 4h with uninfected or chronically HIV-infected T cells. As shown in figure 5A, Tat levels markedly decreased upon co-culture with MOLT-X4 cells, while they were fully rescued in the presence of 3-MA. This result confirms that Env-mediated autophagy flux induction is responsible for Tat degradation. We reproduced the experiments using 8.E5 cells as donor cells. These CD4+ T cells are productively infected, thus expressing Env at the surface but, because they do not express the reverse transcriptase, they do not produce infectious viral particles. With this model, the Env-mediated autophagy induction was even more pronounced as evidenced by the increased and sustained Tat degradation observed in target cells (Fig. 5B).

While viral challenge could rapidly and transiently induce autophagy, productive infection appeared to block this defense mechanism, thus potentially protecting the viral transactivator Tat from degradation. Interestingly, Tat can exert multiple effects on bystander cells when secreted from productively infected cells. For instance, secreted Tat was reported to transactivate the expression of genes under control of the HIV-LTR in bystander cells. To examine whether incoming Tat could be degraded by autophagy, we used HeLa cells expressing CD4 and CXCR4 together with the β-galactosidase under control of the HIV-LTR promoter (MAGICSB cells) (44). MAGICSB cells were co-cultured during 4h and 8h with MOLT-X4 cells in the presence or absence of 3-MA and β-galactosidase activity was measured. An enzymatic activity could be detected in reporter target cells supporting the bystander effect of secreted Tat. Transactivation was significantly increased in the
presence of 3-MA, strongly suggesting that autophagy controls Tat-mediated transactivation of HIV-LTR (Fig. 5C). Because 3-MA could have some side effects possibly affecting Tat secretion from infected cells, we aimed at confirming these results by directly downregulating the expression of essential ATG proteins in target cells. Therefore, MAGIC5B cells were transfected with siRNA directed against Beclin 1, or Atg7, or unrelated siRNA (unr) before co-culture with MOLT-X4 cells. As expected, the level of β-galactosidase activity was increased at both time points of co-culture when Beclin 1 or Atg7 expression were silenced (Fig. 5D). Inversely, autophagy induction should inhibit HIV-LTR transactivation due to Tat degradation (see Fig. 2). Indeed, when MAGIC5B cells were co-cultured with MOLT-X4 cells in the presence of Torin 1, we observed a significant decrease of β-galactosidase activity, inversely correlated with the increased enzymatic activity obtained upon autophagy flux blockade with AP (Fig. 5E). Hence, the effect of drug-mediated autophagy induction on transactivation by Tat appeared to be sustained as evidenced by the decreased transactivation upon 16h of co-culture (Fig. 5E). These data thus show that the autophagy pathway can be a major regulator of Tat-mediated transactivation and viral replication. This conclusion is valid whether Tat is produced intracellularly (i.e. by infected cells) or delivered from the outside (i.e. endocytosed).

Indeed, to confirm that the detected viral promoter transactivation was exclusively Tat-dependent and controlled by autophagy, we took advantage of a previously described Tat mutant that lacks its single tryptophan residue (Tat-W11Y). This mutant retains transactivation activity but is unable to enter bystander cells (35) (Figure 5F). MAGIC5B cells were transfected with a Beclin 1-specific siRNA or a control siRNA, then treated with 200nM of recombinant Tat-WT or Tat-W11Y and β-galactosidase activity was measured after 48h. We observed that, contrary to cells treated with Tat-WT, transactivation was not significant
when Tat-W11Y was used (Fig. 5G). These results confirm that transactivation by incoming Tat is targeted by selective autophagy.

**DISCUSSION**

HIV-1, like other viruses, has to deal with cellular defenses in order to replicate efficiently. Although several cellular HIV-1 restriction factors have been identified, most of them were shown to be affected by viral countermeasures (45). We previously demonstrated that HIV-1 Env induces autophagy in uninfected CD4$^+$ T lymphocytes via the fusogenic function of gp41, leading to their apoptotic cell death (30, 31). In this study, we demonstrate that induction of autophagy is readily detectable shortly upon viral challenge in an Env-dependent manner, while being compromised later in time. Autophagic activity is inversely correlated with HIV-1 production. We further provide evidence that autophagy, when pharmacologically induced in productively infected CD4$^+$ T cells, leads to a significant decrease in viral production thus identifying this cellular pathway as an HIV-1 restriction mechanism. This observation led us to decipher the molecular mechanism of the autophagy-mediated antiviral effect. A two-hybrid screen revealed a strong and specific interaction between p62 (also called SQSTM1), an autophagy receptor, and the viral transactivator Tat. We first confirmed the interaction between both proteins at the cellular level in pull-down assays and confirmed that Tat expression levels were modulated in cells upon autophagy activation or inhibition. We then demonstrated that Tat expression was significantly increased in p62-deficient cells, suggesting that p62 could be a mediator of Tat degradation by selective autophagy. We therefore analyzed the domains of p62 possibly involved in the interaction with Tat. Surprisingly, the interaction between Tat and p62 was not relying on a functional UBA domain of p62, suggesting that ubiquitination would not regulate p62-mediated Tat
degradation, in contrast to the general paradigm reported for other substrates (46).
Consistently, Tat mutations at the level of lysines which were previously shown to regulate
Tat stability and activity did not prevent its degradation upon autophagy induction. Although
we cannot exclude modification of other residues or the involvement of unidentified cellular
proteins belonging to the complex Tat/p62, our data represent the first demonstration of
selective autophagic degradation of a viral transactivator. Indeed, in a context of viral
infection, a selective p62-mediated degradation has only been demonstrated for two
structural viral proteins, the capsid protein of the chikungunya virus (CHIKV) and the capsid
protein of the Sindbis virus (SIN) (4, 47). In the case of CHIKV, p62 binds to ubiquitinated
capsid and targets it to autophagic degradation while in the case of the SIN, and as
reminiscent of our data for Tat, the interaction between p62 and the SIN capsid does not
require the p62 UBA domain, highlighting a potential original mechanism by which p62
recognizes autophagic substrates. As p62 could frequently interacts with viral proteins (48),
it would be interesting to decipher the molecular mechanism behind this ubiquitin-
independent p62-mediated autophagic degradation, with a particular emphasis on the
identification of putative other cellular partners linking p62 to its substrates. One potential
candidate is the histone deacetylase HDAC6 whose deacetylase activity was shown to be
regulated upon interaction with p62 (49). Furthermore, HDAC6 was also reported to
deacetylate Tat, leading to a decrease in Tat transactivation activity (50).
Although cellular factors are involved in HIV-1 transcription, Tat is absolutely required for
HIV-1 replication since it is needed for the elongation of viral transcripts (20). Tat is thus a
perfect target to shut down viral production. Interestingly, Tat was shown to be actively
secreted from infected cells and captured by several cell types (21, 42). Our results suggest
that incoming Tat is also a target for autophagic degradation following internalization by
bystander cells. The consequences of this degradation on the different known effects of Tat, and in particular on the homeostasis of target cells, warrants further investigation.

We uncovered that autophagy is induced by HIV-1 Env at the very first steps of infection. This Env-induced autophagy is timely regulated and initially triggers the degradation of any incoming Tat, avoiding the death of the target cells long enough to allow the virus to initiate its replication. If productive infection of the target cells proceeds, the virus blocks autophagy, and Tat, thereby protected from degradation, can fulfill its transcriptional role, enabling robust viral production.

The regulation of intracellular Tat concentration is tightly regulated. Indeed, we demonstrated here that Tat can be degraded by basal constitutive autophagy and upon Env-induced autophagy. Tat was also reported to inhibit the autophagy process in uninfected cells (33, 34), underlining the complex relationship between autophagy and this viral protein. This also seems to be the case for another retroviral transactivator, the HTLV-1 Tax protein. Indeed, the group of KT Jeang demonstrated that Tax is a substrate for autophagy degradation, but the underlying mechanism is still unknown. They also demonstrated that Tax is able to block the degradative phases of autophagy suggesting that this viral protein could control its own stability and turnover (51).

Highly active antiretroviral therapy (HAART) can efficiently block viral replication and reduce the levels of circulating virus below the detection limit. Despite its efficacy, the virus is not eradicated due to the establishment of latent but replication-competent proviruses in reservoir cells probably located in peripheral blood and tissues. Viral latency is characterized by HIV-1 LTR-transcriptional repression and, interestingly, a hallmark of this process is the low level of Tat. Thus, specific degradation of Tat by autophagy could adversely contribute to
the establishment of HIV-1 latency which should be taken into account in the prospect of future antiviral strategies.

Since Tat is absolutely required for viral transcription, many therapeutic strategies targeting this viral protein have been considered, such as Tat antagonists (52), dominant-negative Tat (53, 54), Tat inhibitory peptides (55-58), or siRNAs against Tat (59-61). However, none of these strategies has been successful to date. The autophagy-mediated degradation of Tat presented here could represent a new way to target this viral protein in infected cells, allowing to block viral transcription and thus viral replication. Indeed, while HAART acts directly on viral enzymatic proteins, the induced degradation of Tat by autophagy could represent a new strategy based on a cellular response. Interestingly, some sirolimus-derived compounds (rapamycin, rapamune), which are strong inducers of autophagy and already used in therapeutics were shown to possess anti-HIV-1 properties (62). Recently, Campbell and Spector demonstrated that vitamin D3 inhibits HIV replication through induction of autophagy (63). It would be, therefore, interesting to examine the autophagic-induced degradation of Tat in these contexts and its possible outcome on inhibition of HIV replication.

The results obtained in our study provide new evidence of the antiviral action of autophagy and underlie why the viruses have evolved strategies to block this process.

ACKNOWLEDGMENTS
The work was supported by institutional funds from the Centre National de la Recherche Scientifique (CNRS) and the Montpellier University I and II (UMI and UMII), and grants from Sidaction and the Agence Nationale de Recherche sur le SIDA (ANRS). Sophie Sagnier was the recipient of a fellowship from ANRS and Sidaction. We thank Dr. M. Benkirane for providing
the Tat-K71R construct, Dr. T. Johansen for the GST-p62 plasmids, Dr. T. Yoshimori for the GFP-LC3 construct and Dr. N. Chazal for the Gag expression vector. The anti-p24 antibody was obtained through the NIH AIDS Reagent Program, Division of AIDS, NIAID, NIH.

FIGURE LEGENDS

Figure 1: Autophagy has an anti-HIV-1 effect in CD4⁺ T lymphocytes

Primary CD4⁺ T cells (A) or Jurkat cells (B) were infected with HIV-1 at a MOI of 1 for 3 days. Cells were then extensively washed to eliminate excess of free viruses and cultured for 24h in the presence of 2 µM Torin 1 to induce autophagy. HIV Gag-p24 levels were quantified by ELISA in the culture supernatants. (C) Chronically infected MOLT-X4 cells were treated for 24h with 2 µM Torin 1 and HIV Gag-p24 concentration was quantified in the culture supernatants by ELISA. Data are representative of triplicates from at least 3 independent experiments.

Figure 2: Tat interaction with p62 leads to its selective degradation by autophagy

(A) HEK cells were co-transfected with the FLAG-Tat vector and the GST or GST-p62 plasmid. 24h post-transfection, cells were lysed and lysates were subjected to GST pull-down before immunoblotting with anti-FLAG or anti-GST Ab. A fraction of lysates was preserved and used as an input control and immunoblotted with the anti-FLAG Ab. The result is representative of at least 5 different experiments. (B) HEK cells were transfected with plasmids expressing FLAG-Tat. After 24h, the transfected cells were treated or not with 2 µM Torin 1 in the presence or absence of antiproteases (AP: E64d+pepstatin A, 10µg/ml each)
for 3h. The expression level of the FLAG-Tat was revealed by western blot using anti-FLAG Ab. Levels of expression were quantified by densitometry and normalized to GAPDH expression levels. Data are representative of at least 8 independent experiments for FLAG-Tat. (C) HEK cells were transfected with plasmids expressing Flag-Tat, FLAG-Nef, Flag-Vif or Gag. After 24h, the transfected cells were treated or not with 2 μM Torin for 3h. The expression level of the FLAG-tagged proteins or Gag was revealed by western blot using anti-FLAG or anti-p24\textsuperscript{Gag} Ab, respectively. Levels of expression were quantified by densitometry and normalized to GAPDH expression levels. Data are representative of at least 3 independent experiments. (D) Chronically infected MOLT-X4 cells were treated or not for 3h with 2 μM of Torin 1 in the presence or absence of AP. Cell lysates were then subjected to immunoblotting with anti-Tat Ab and anti-GAPDH Ab as loading control. Tat expression levels were quantified by densitometry and normalized to GAPDH protein levels. Data are representative of at least 3 independent experiments. (E) HEK cells, previously transfected with unspecific (siCT) or ATG7-specific siRNA (siAtg7), were transfected with the FLAG-Tat vector for 24h. Cells were then treated or not with 2 μM of Torin 1 for 3h before lysis. Cell lysates were immunoblotted with anti-Atg7 Ab, anti-FLAG Ab or anti-GAPDH Ab as loading control. Expression levels of Atg7 (left panels) and Tat (right panels) were quantified by densitometry and normalized to GAPDH protein levels. Data are representative of at least 3 independent experiments. (F) HEK cells were transfected with p62-specific siRNA (sip62) or control siRNA (siCT) and then transfected with the plasmid expressing FLAG-Tat. The following day, cells were lysed and p62 and Tat levels were assessed in lysates by Western blot using Abs against p62 and FLAG. Sample loading was controlled by immunoblotting with anti-GAPDH Ab. Expression levels of p62 (left panels) and Tat (right panels) were quantified
by densitometry and normalized to GAPDH protein levels. Data are representative of 4 independent experiments.

**Figure 3: p62-dependent interaction of Tat with LC3**

(A) HEK cells were co-transfected with the FLAG-Tat vector and plasmids expressing either GST (lanes 1 and 4), GST-LC3 (lane 2), GST-LC3F52A (lane 3), GST-p62 (lane 5) or GST-p62ΔLIR (lane 6). 24h post-transfection, cells were lysed and lysates subjected to GST pull-down before immunoblotting with anti-FLAG Ab and anti-GST Ab. In each case, a fraction of lysates was preserved and used as an input control and immunoblotted with the anti-FLAG Ab. (B) HEK cells were co-transfected with plasmids expressing FLAG-Tat and either GST alone (lane 1), GST-p62 (lane 2), GST-p62ΔUBA (lane 3) or GST-p62ΔPB1 (lane 4) before GST pull-down. Results are representative of at least 3 independent experiments. (C) HEK cells transfected with plasmids expressing wt FLAG-Tat (Tat WT), or mutated forms of Tat (Tat K71R or Tat K50-51A) were treated or not with 2 µM of Torin 1 for 3h. Lysates obtained from each condition were used to analyze the expression levels of Tat and GAPDH as previously described. FLAG-Tat levels were quantified by densitometry upon normalization with GAPDH expression levels in the corresponding samples.

**Figure 4: Autophagy is induced at early steps of HIV-1 infection**

(A) HEK/CD4/CXCR4 cells, previously transfected with a plasmid expressing GFP-LC3, were co-cultured with either MOLT cells (CT, negative control, hatched line) or chronically infected MOLT-X4 cells (HIV, plain line) for indicated times. The number of autophagic HEK/CD4/CXCR4 cells was counted by 3 different experimenters and the result is the mean of 3 independent experiments. The percentage of autophagic cells obtained after co-culture
with MOLT-X4 cells was normalized with the percentage of autophagic cells obtained after co-culture with MOLT cells. A representative pattern of GFP-LC3 puncta in HEK/CD4/CXCR4 cells upon 4h of co-culture with MOLT-X4 cells is presented on the left hand side and compared to the fluorescence pattern obtained upon 4h of co-culture with control MOLT cells. In parallel, the percentage of HIV-infected cells was quantified by flow cytometry using the anti-p24 Ab. (B) Human primary CD4\(^+\) T cells were transfected with a plasmid expressing GFP-LC3 and co-cultured with HEK cells (negative control) or Env-transfected HEK cells during 2h or 4h. Quantification was performed as described above and the results are presented as a mean fold of each condition from 3 independent experiments. A representative pattern of GFP-LC3 puncta in primary CD4\(^+\) T cells upon 4h of co-culture with HEK-Env cells is presented and compared to the fluorescence pattern obtained upon 4h of co-culture with control HEK cells. (C) Human primary CD4\(^+\) T cells were co-cultured with HEK cells expressing Env, or not, for 4h and autophagic vacuoles were observed by transmission electron microscopy. The percentage of autophagic cells is presented. (D) Human primary CD4\(^+\) T cells were co-cultured with HEK cells expressing Env, or not, during 4h in the presence or absence of AP. CD4\(^+\) T cells were harvested and lysates were immunoblotted with anti-LC3 Ab and anti-GAPDH Ab as loading control. LC3-II levels were quantified by densitometry and normalized with GAPDH expression levels. (E) HEK/CD4/CXCR4 cells were transfected with the FLAG-Tat vector and then co-cultured with MOLT cells (negative control) or with MOLT-X4 cells during 4h and 48h. Suspension cells were removed by washing and autophagy induction was monitored in the lysates of target cells upon immunoblotting with anti-LC3 Ab (left panel). Tat levels were assessed with the anti-FLAG Ab (right panel) while sample loading was controlled with the anti-GAPDH Ab for each
condition. LC3-II and Tat levels were quantified by densitometry upon normalization with GAPDH expression levels in the corresponding samples.

Figure 5: Autophagy-mediated Tat degradation inhibits HIV-1 LTR activation and viral replication

(A) HEK/CD4/CXCR4 cells transfected with the FLAG-Tat vector were co-cultured with uninfected (MOLT) or chronically HIV-1-infected cells (MOLT-X4) cells during 4h, in the presence or absence of 10 mM 3-MA. Tat expression was monitored by Western blot using the anti-FLAG Ab and quantified upon normalization with GAPDH levels. (B) HEK/CD4/CXCR4 cells, transfected as above, were co-cultured for 4h with effector control cells (Env negative) or cells expressing HIV-1 envelope (8.E5 cells). Tat detection and quantification was done as previously described. (C) MAGIC5B cells were co-cultured with MOLT-X4 cells during 4h or 8h in the presence or absence of 3-MA. After cell lysis, β-galactosidase activity was quantified by luminescence and normalized to the condition in absence of 3-MA for each time of co-culture. Data represent the mean +/- SE of at least 3 independent experiments. (D) MAGIC5B cells were transfected with control (CT) or Beclin 1 (Bec1) or Atg7-specific siRNA during 16h. Transfected cells were then co-cultured with MOLT-X4 cells during 4h. The cells were washed, harvested, and then lysed. A fraction of lysates was kept to control Beclin 1, ATG7 and GAPDH levels by immunoblotting (left panels) while remaining lysates were used to measure β-galactosidase activity, normalized to the activity obtained from cells transfected with CT siRNAs for each time point. Data are mean +/- SE of 4 independent experiments. (E) MAGIC5B cells co-cultured with MOLT-X4 cells were incubated or not with 2 µM of Torin 1 for 16h in the presence or absence of AP. Fold induction of β-galactosidase activity was calculated as the enzymatic activity obtained in treated cells compared to the one in
untreated cells. Data are representative of at least 3 independent experiments. (F) MAGIC5B cells were incubated for 48h with 200 nM of recombinant wild-type Tat (Tat), mutant Tat (W11Y) or medium alone (Ct) before assaying the β-galactosidase activity. (G) MAGIC5B cells, treated as in (D), were incubated for 48h with 200 nM of recombinant Tat or W11Y. A fraction of lysates was kept to control for Beclin 1 and GAPDH levels by immunoblotting while remaining lysates were used to measure β-galactosidase activity. Data are representative of at least 5 independent experiments.
Figure 1: Autophagy has an anti-HIV-1 effect in CD4+ T lymphocytes

Primary CD4+ T cells (A) or Jurkat cells (B) were infected with HIV-1 at a MOI of 1 for 3 days. Cells were then extensively washed to eliminate excess of free viruses and cultured for 24 h in the presence of 2 μM Torin 1 to induce autophagy. HIV-Gag p24 levels were quantified by ELISA in the culture supernatants. (C) Chronically infected MOLT-4 cells were treated for 24 h with 2 μM Torin 1, and HIV-Gag p24 concentration was quantified in the culture supernatants by ELISA. Data are representative of triplicates from at least 3 independent experiments.
Figure 2: Tat interaction with p62 leads to its selective degradation by autophagy

HEK cells were co-transfected with the FLAG-Tat vector and the GST or GST-p62 plasmid. 24 h post-transfection, cells were lysed and lysates were subjected to GST pull-down before immunoblotting with anti-FLAG or anti-GST Ab. A fraction of lysates was preserved and used as an input control and immunoblotted with the anti-FLAG Ab. The results are representative of at least 5 different experiments. (B) HEK cells were transfected with p62 and Flag-expressing Flag-Tat. After 24 h, the transfected cells were treated or not with 2 μM Torin 1 in the presence or absence of anti-interactes (AP: to 46-kDa protein A, 10 μg/ml each) for 3 h. The expression level of the FLAG-Tat was revealed by Western blot using anti-FLAG Ab. Levels of expression were quantified by densitometry and normalized to GAPDH expression levels. Data are representative of at least 8 independent experiments for FLAG-Tat. (C) HEK cells were transfected with p62 and Flag-expressing Flag-Tat, Flag-NAF, Flag-VIF or Gag. After 24 h, the transfected cells were treated or not with 2 μM Torin 1 for 3 h. The expression level of the Flag-tagged proteins or Gag was revealed by Western blot using anti-Flag or anti-p24 Ab, respectively. Levels of expression were quantified by densitometry and normalized to GAPDH expression levels. Data are representative of at least 8 independent experiments. (D) Chronically infected MOLT-4 cells were treated or not for 3 h with 2 μM of Torin 1 in the presence or absence of AP. Cell lysates were then subjected to immunoblotting with anti-Tat Ab and anti-GAPDH Ab as loading control. Tat expression levels were quantified by densitometry and normalized to GAPDH protein levels. Data are representative of at least 8 independent experiments. (E) HEK cells, previously transfected with either specific siRNAs (siRNA) or ATG7 siRNA, were transfected with the Flag-Tat vector for 24 h. Cells were then treated or not with 2 μM of Torin 1 for 3 h before lysis. Cell lysates were immunoblotted with anti-Mg2 Ab, anti-FLAG Ab or anti-GAPDH Ab as loading control. Expression levels of Mg2 (left panels) and Tat (right panels) were quantified by densitometry and normalized to GAPDH protein levels. Data are representative of at least 3 independent experiments. (F) HEK cells were transfected with p62-specific siRNA (si-p62) or control siRNA (si-CT) and then transfected with the Flag-Tat vector. The day after, cells were lysed and p62 and Tat levels were assessed by Western blot using Abs against p62 and Tat. Sample loading was controlled by immunoblotting with anti-GAPDH Ab. Expression levels of p62 (left panel) and Tat (right panel) were quantified by densitometry and normalized to GAPDH protein levels. Data are representative of 4 independent experiments.
Figure 3: p62-dependent interaction of Tat with LC3

(A) HEK cells were co-transfected with the FLAG-Tat vector and plasmids expressing either GST (lane 1 and 4), GST-LC3 (lane 2), GST-LC3FS2A (lane 3), GST-p62 (lane 5) or GST-p62JUXR (lane 6). 24h post-transfection, cells were lysed and lysates subjected to GST pull-down before immunoblotting with anti-FLAG Ab and anti-GST Ab. In each case, a fraction of lysates was preserved and used as an input control and immunoblotted with the anti-FLAG Ab. (B) HEK cells were co-transfected with plasmids expressing FLAG-Tat and either GST alone (lane 1), GST-p62 (lane 2), GST-p62JUXR (lane 3) or GST-p62JUXR (lane 4) before GST pull-down. Results are representative of at least 3 independent experiments. (C) HEK cells transfected with plasmids expressing GST-FLAG-Tat (Tat WT), or mutated forms of Tat (Tat K71R or Tat K50-S1A) were treated or not with 2 μM of Torin 1 for 3h. Lysates obtained from each condition were used to analyze the expression levels of Tat and GAPDH as described before. FLAG-Tat levels were quantified by densitometry upon normalization with GAPDH expression levels in the corresponding samples.
Figure 4A – C: Autophagy is induced at early steps of HIV-1 infection

(a) HEK293/CD4/CCR5 cells previously transfected with a plasmid expressing GFP-LC3, were co-cultured with either MOI Tet cells (no control, hatched line) or chronically infected MOI Tet cells (HIV, plain line) for indicated times. The number of autophagic HEK293/CD4/CCR5 cells was counted by 5 different experiments and the result is the mean of 5 independent experiments. The percentage of autophagic cells obtained after co-culture with MOI Tet cells was normalized with the percentage of autophagic cells obtained after co-culture with MOI Tet cells. A representative pattern of GFP-LC3 punctae in HEK293/CD4/CCR5 cells upon 4h of co-culture with MOI Tet cells is presented on the left hand side and compared to the fluorescence pattern obtained upon 4h of co-culture with control MOI Tet cells. The percentage of HIV infected cells was quantified by flow cytometry using the anti-p24 Ab. (b) Human primary CD4+ T cells were transfected with a plasmid expressing GFP-LC3 and co-cultured with HEK cells (negative control) or Env-transfected HEK cells during 2h or 4h. Quantification was performed as described above and the results are presented as a mean fold of each condition from 3 independent experiments. A representative pattern of GFP-LC3 punctae in primary CD4+ T cells upon 4h of co-culture with HEK-Env cells is presented and compared to the fluorescence pattern obtained upon 4h of co-culture with control HEK cells. (c) Human primary CD4+ T cells were co-cultured with HEK cells expressing Env, or not, for 4h and autophagic vacuoles were observed by transmission electron microscopy. The percentage of autophagic cells is presented.
Figure 4D–F. Autophagy is induced at early steps of HIV-1 infection.

(Left panel) HEK/CD4/CXCR4 cells were co-cultured with the GFP-LCS vector were co-cultured for 4h with effector cells expressing 8T5 cells or not (CEM cells). Env in the presence or absence of TZO (a peptide inhibiting the gag protease) was detected by fluorescence microscopy as before. Data are representative of 3 independent experiments. More than 100 cells were counted by 3 investigators. (Middle panel) Human primary CD4+ T cells were co-cultured with HEK cells expressing Env, or not, during 4h in the presence of anti-Env. CD4+ T cells were harvested and lysed were immunoblotted with anti-LC3 Ab and anti-GAPDH Ab as loading control. LC3-II levels were quantified by densitometry and normalized with GAPDH expression levels. (Right panel) HEK/CD4/CXCR4 cells were transfected with the FLAG-Tat vector and then co-cultured with MOLT cells (negative control) or with MOLT-K4 cells during 4h and 48h. Supernatant cells were removed by washing and autophagy induction was monitored in the lysates of target cells upon immunoblotting with anti-LC3 Ab (left panel). Tat levels were assayed with the anti-FLAG Ab (right panel). All samples were loaded with the anti-GAPDH Ab for each condition. LC3-II and Tat levels were quantified by densitometry upon normalization with GAPDH expression levels in the corresponding samples.
Figure 5: Autophagy-mediated Tat degradation inhibits HIV-1 LTR activation and viral replication

(A) H9/LXO/CMV cells were co-cultured with the FLAG-Tat vector or infected with MOLT-4 (MOLT-4A) cells during 6h in the presence or absence of 10 μM 3-MA. Tat expression was monitored by western blot using the anti-FLAG Ab and quantified upon normalization with GAPDH levels. (B) H9/ODC/KCR4 cells, transfected as above, were co-cultured for 4h with effector control cells (Env-negative) or cells expressing HIV-1 envelope (HIV-1). Tat detection and quantification was done as previously described. (C) MFI/CB9 cells were co-cultured with MOLT-4A cells during 4h or 8h in the presence or absence of 3-MA. After cell lysis, β-galactosidase activity was quantified by luminescence and normalized to the condition in absence of 3-MA for each time of co-culture. Data represent the mean ± SEM of at least 3 independent experiments. (D) MFI/CB9 cells were transfected with control (CT) or Beclin 1 (Becn1) or Atg7-specific siRNA during 6h. Transfected cells were then co-cultured with MOLT-4A cells during 4h. The cells were washed, harvested, and then lysed. A fraction of lysates was kept to control Becn1 and GAPDH levels by immunoblotting (left panel) while remaining lysates were used to measure β-galactosidase activity, normalized to the activity obtained from cells transfected with CT-siRNA for each time point. Data are mean ± SD of 4 independent experiments. (E) MFI/CB9 cells co-cultured with MOLT-4A cells were incubated or not with 2 μM of Torin 1 for 18h in the presence or absence of AP. Fold induction of β-galactosidase activity was calculated as the enzymatic activity obtained in treated cells compared to the one in untreated cells. Data are representative of at least 3 independent experiments. (F) MFI/CB9 cells were incubated for 48h with 200 nM of recombinant wild-type Tat (Tat), mutant Tat (W11Y) or medium alone (D) before assaying the β-galactosidase activity. Data are representative of at least 5 independent experiments.
