ABSTRACT

Twelve cationic helicenes and one triangulene were tested for the specific labeling of mitochondria from algal cells. Octyl ester derivative **5** readily penetrates algal cells and gives rise to clear fluorescence patterns when it is used at concentrations in the μM range. Under these conditions, cell structures are well preserved and cell survival is not compromised. Cationic helicene compounds such as **5** provide new useful tools for examining the mitochondrial network and its dynamics including fission and fusion events.

Introduction

Fluorophores have been widely used for visualizing specific subcellular structures with high spatial and temporal resolution in living cells.¹ Both fluorescent proteins and chemical dyes coupled to proteins have provided robust tools for studying the localization and dynamics of a large set of proteins.² In addition, specific dyes have been developed for the labeling of specific organelles.³ As an example, the Mitotracker dyes are targeted specifically to mitochondria and can be used to follow mitochondrial fusion and fission events. Some of these Mitotracker dyes require an electrochemical potential across the mitochondrial envelope to enter these organelles while others are taken up in the absence of such a potential. Thus these dyes provide important information on the energetic state of mitochondria. They have been used extensively in animal and plant cells but less in algal cells. Although Mitotracker dyes have been used successfully to monitor mitochondrial fusion in cells of the green unicellular alga *Chlamydomonas reinhardtii*,⁴ in our hands they gave rise to variable results. Other dyes specific for mitochondria in *Chlamydomonas* include rhodamine 123, which acts as a sensitive potentiometric dye in this alga.⁵ Here we have screened several recently synthesized cationic dyes, which are potential candidates for specifically staining cellular organelles – and late endosomes and mitochondria in particular.⁶ This study concerns the use of these fluorophores, and others, for labelling mitochondria in algal cells.

Results and discussion

We tested twelve cationic helicenes and one triangulene compound (Fig. 1).⁷ Diaza [4]helicenes **1–7** were prepared in two to five steps from 1,3-dimethoxybenzene.⁸ Azaoxa **8–10** and diaza **11–12** [6]helicenes were prepared in six steps from 2-methoxynaphthalene using a single common advanced intermediate in a highly convergent process.⁹ Diazaoxa triangulene **13** was also prepared from 1,3-dimethoxybenzene in four steps.^{6a} Some of the helicenes can be isolated as single enantiomers in gram-scale but, for this study, these compounds were used as racemates.¹⁰ Details are provided in the Materials and methods section.

Fig. 1 Structure of cationic helicene and triangulene fluorophores **1–13**.

They display absorption and fluorescence within the transparency window of biological media^{8c,11} and have proven to act as efficient probes for bio-imaging,^{6b,12} binding selectively DNA¹³ or behaving as chiroptical switches.¹⁴ Moreover, their significant Stokes shifts, varying from 1090 to 1580 cm^{-1} (for **11** and **5**, respectively), allow one to perform bio-imaging experiments with high signal to noise ratio (Fig. 2). For labeling subcellular structures of *Chlamydomonas* cells, we used a Leica confocal SP 5 microscope with tunable fluorescence excitation and emission wavelengths. Cells of *Chlamydomonas* in exponential growth phase were incubated for 10–20 min with these compounds. The absorption and fluorescence emission spectra of some of these helicenes are shown in Fig. 2; compounds **1**, **5**, **10**, **11** and **13** were selected as representative examples. For the detection of fluorescence signals, we chose an excitation wavelength at 550 nm and measured fluorescence emission from 580 to 620 nm to minimize interference with the endogenous chlorophyll fluorescence.

Fig. 2 Absorption (A) and fluorescence (B) spectra of **1** ($\lambda_{abs} = 616$ nm, $\lambda_{em} = 667$ nm Stokes shift: 1240 cm^{-1} , 51 nm), **5** ($\lambda_{abs} = 593$ nm, $\lambda_{em} = 653$ nm, Stokes shift: 1580 cm^{-1} , 60 nm), **10** ($\lambda_{abs} = 562$ nm, $\lambda_{em} = 613$ nm, Stokes shift: 1480 cm^{-1} , 51 nm), **11** ($\lambda_{abs} = 614$ nm, $\lambda_{em} = 658$ nm, Stokes shift: 1090 cm^{-1} , 44 nm) and **13** ($\lambda_{abs} = 549$ nm, $\lambda_{em} = 594$ nm, Stokes shift: 1380 cm^{-1} , 45 nm).

Several of the compounds tested gave rise to specific fluorescence signals ([Table 1](#)). Chlorophyll autofluorescence was measured with excitation at 470 nm and fluorescence emission from 650 to 700 nm. Of the thirteen compounds tested, five gave rise to a specific signal (**1**, **2**, **4**, **5** and **10**). Compounds **5** and **10** gave the strongest response ([Table 1](#)). In particular, we noticed that extension of the ester-C8 chain of **5** to C18 in compound **6** led to a drastic decrease of staining. This is in sharp contrast to what has been observed for the labelling of mitochondria with HeLa, U87MG and PC3 cell lines.^{6b} We chose compounds **4** and **5** ([Fig. 1](#)) for further experiments and used them at a concentration of 1 μM . Under these conditions, the fluorescence signal can be readily detected, the cellular structure is well preserved and cell survival is not compromised. To identify the subcellular structures labeled by these fluorophores, we used several reporter lines expressing proteins of known cellular location fused to Yellow Fluorescent Protein (YFP).¹⁵ These lines include proteins of the cytoplasm, nucleus, endoplasmic reticulum, mitochondria and chloroplast. YFP fluorescence was detected using excitation at 510 nm and fluorescence emission between 520 nm and 545 nm. Comparison of the fluorescence signals obtained with YFP fused to the mitochondrial protein CAH4 (carbonic anhydrase) and helicenenes **4** and **5** revealed overlapping fluorescence patterns indicating that these compounds label specifically mitochondria ([Fig. 3](#)).

Fig. 3 Helicene **5** labels mitochondria. Cells of *Chlamydomonas* containing Mit-YFP (YFP-mitochondria) were treated with 1 μ M Helicene **5** and immobilized on glass slides treated with poly l-lysine. They were examined by phase contrast (left column, grey) and fluorescence microscopy on a Leica confocal SP 5 microscope with the following settings: Helicene **5** fluorescence excitation at 550 nm and fluorescence emission from 580–620 nm (labelled Hel **5**, middle column, magenta); YFP-mitochondria, fluorescence excitation at 510 nm and fluorescence emission from 520–545 nm (labelled YFP-mito, right column, green). Bars 2 μ m.

Table 1 Excitation emission conditions

Target	Excitation wavelength	Emission wavelength window
Fluorophores 1–13	550 nm	580–620 nm
YFP	510 nm	520–545 nm
Mitotracker deep red	620 nm	655–680 nm

Comparison with the fluorescence obtained with the Mitotracker dye Deep Red further confirmed the mitochondrial location of **5** (Fig. 4). The similarities of fluorescence patterns of **5** with those of mitochondrial protein CAH4 were striking and seemed even better correlated than those obtained with the Mitotracker dye.

Fig. 4 Fluorescence patterns of Helicene **5** and Mitotracker Deep Red are similar. Cells of *Chlamydomonas* containing YFP-mitochondria (labelled YFP-mito, upper right, green) were treated with 1 μ M Helicene **5** (labelled Hel **5**, upper left, magenta) and 1 μ M Mitotracker Deep Red (labelled DR-mito, lower left, cyan) and immobilized on glass slides treated with poly L-lysine. Fluorescence settings were as in [Fig. 3](#) and for Mitotracker Deep Red: fluorescence excitation at 620 nm and fluorescence emission from 655 to 680 nm. Bar 2 μ m.

To further test the specificity of mitochondrial labeling with **5**, we compared its fluorescence patterns with those obtained with two YFP-tagged chloroplast proteins, the stromal protein Rubisco and Tic20, a component of the protein translocon of the inner chloroplast membrane. As seen in [Fig. 5](#), the fluorescence patterns obtained with these proteins were very different from those of **5** indicating that this compound does not bind or enter chloroplasts.

Fig. 5 Cell fluorescence patterns of Helicene **5** are different from those of chloroplast proteins. A. Comparison of fluorescence of Helicene **5** (labelled Hel **5**, middle, magenta) with the small subunit of Rubisco fused to YFP (labelled YFP-Rub, right, green) (chloroplast stromal protein). B. Comparison of fluorescence of Helicene **5** (labelled Hel **5**, middle column, magenta) with Tic20-YFP (labelled YFP-Tic20, right column, green) (chloroplast inner envelope protein). Bars 2 μ m.

To examine whether the entrance of **5** into mitochondria requires an electrochemical potential, cells were treated with 5 μ M FCCP to collapse this gradient. Under these conditions, no fluorescence was detected indicating that this fluorophore enters mitochondria only in the presence of an electrochemical gradient ([Fig. 6A](#)). Treatment of the cells with myxothiazol, an inhibitor of the bc1 complex and hence of the respiratory electron transfer chain did not significantly affect the fluorescence of **5** as compared to untreated cells ([Fig. 6B](#)). This result was expected since, under these conditions, the ATP synthase acts as an ATPase and generates an electrochemical gradient by pumping protons into the mitochondrial matrix.

Fig. 6 Fluorescence of Helicene **5** of *Chlamydomonas* cells requires an electrochemical potential across the mitochondrial membrane. A. *Chlamydomonas* cells containing MitYFP were treated with 5 μ M FCCP (labelled + FCCP, lower row) or without (upper row, labelled – FCCP). Whereas mitochondrial YFP staining (labelled YFP-mito, right column, green) stays intact, the Helicene **5** staining (labelled Hel **5**, middle column, magenta) disappears upon FCCP treatment (lower row, middle). B. Cells were treated with 5 μ M myxothiazol (lower row, labelled + MXT) or without (upper row, labelled – MXT). Mitochondrial YFP staining (labelled YFP-mito, right column, green) as well as Helicene **5** staining (labelled Hel **5**, middle column, magenta) are undisturbed by myxothiazol treatment. Bars 2 μ m.

Conclusions

We have shown that a small number of cationic helicene and triangulene compounds can be used for specifically labeling mitochondria from algal cells. These compounds are remarkably different from those targeting mitochondria in HeLa, PC3 or U87MG cancer cell lines.^{6b} It is most likely that they can be utilized for the same purpose in other organisms. Helicene **5** readily penetrates algal cell and gives rise to clear fluorescence patterns when it is used at concentrations in the μM range. Under these conditions cell structures are well preserved and cell survival is not compromised. Thus, helicene compounds provide new useful tools for examining the mitochondrial network and its dynamics including fission and fusion events. Another interesting property of some of these helicenes is their chemiluminescence.¹⁶ In fact, the luminescence of some of these compounds can be triggered by oxidations or reductions and they could hence be potentially used to monitor the cellular redox environment. However, we were unable to detect any (bio)luminescence with the compounds tested so far.

Materials and methods

The *Chlamydomonas* strains used in this study were wild type 137C, and several derivatives of cmj30 expressing proteins in the nucleus, mitochondria, chloroplast, endoplasmic reticulum, cytoplasm tagged with YFP¹⁵ and obtained from Dr Martin Jonikas and Silvia Ramundo. Cells were grown in TAP medium with an irradiance of $60 \mu\text{mol m}^{-2} \text{s}^{-1}$ at 25 °C.

Luminescence

Fluorescence quantum yields in acetonitrile of cationic dyes (relative to cresyl violet (MeOH, 54%)) were previously reported in the literature: **1** ($\varphi = 13\%$), **4** ($\varphi = 37\%$), **8** ($\varphi = 22\%$) and **11** ($\varphi = 31\%$).^{8c,11}

Fluorophores

Fluorophores **1–7** were obtained in no more than four synthetic steps from tris(2,6-dimethoxy)triarylcarbenium **14**. The [4]helicene scaffold was built by successive nucleophilic aromatic substitutions of MeO groups by primary amine nucleophiles ($R = n\text{Pr}$, $n\text{Oct}$) at 90 °C in DMF for 1 h.^{8b,10b} Access to ester derivatives **3–7** required a multi-step sequence. First, the regioselective Vilsmeier–Haack formylation of **1** followed by a Pinnick-Kraus oxidation led to the formation of a carboxylate derivative.^{8c} Conversion to the corresponding acyl chloride and addition of excess of alcohols yielded esters **3–7** in high yields (Scheme 1). For the preparation of triangulene **13**, triarylcarbenium **14** was treated with hydrazine and then *n*-octylamine to afford non-symmetrical [4]helicene **15**.¹⁷ Heating this compound in molten pyridinium chloride led to **13** in 85% yield. Azaoxa [6]helicenes **8–10** were obtained by mixing precursor **16** with an excess of primary amine in acetonitrile.⁹ Higher temperature and microwave irradiation allowed the access to diaza [6]helicenes **11** and **12**.

Scheme 1 Synthesis of cationic dyes. [a] RNH_2 (25 equiv.), DMF, 90 °C, 1 h. [b] POCl_3 (24 equiv.), DMF, 90 °C, 8 h. [c] NaH_2PO_4 (1 equiv.), H_2O_2 , MeCN, 60 °C, 1 h. [d] (i) SOCl_2 (6 equiv.), CH_2Cl_2 , 25 °C, 10 min; (ii) $\text{R}'\text{OH}$, (5–15 equiv.), 25 °C, 10–15 min. [e] $\text{H}_2\text{N}-\text{NH}_2 \cdot \text{H}_2\text{O}$ (2.5 equiv.), MeCN, 25 °C, 30 min. [f] $n\text{-OctNH}_2$ (25 equiv.), DMF, 90 °C, 16 h. [g] Pyr-HCl , 160 °C, 38 h. [h] RNH_2 , MeCN, 70–90 °C. [i] RNH_2 , NMP, MW, 170 °C, 10 min.

The fluorophores were prepared in 10 mM stock solutions in DMSO. They were first tested on *Chlamydomonas* cells at a concentration of 10 μM to check whether they could enter the cells and finally used at a concentration of 1 μM .

Confocal microscopy and image analysis

For labeling, cells were mixed with their respective dyes diluted in cell culture medium and incubated for 10 to 20 minutes. Before imaging cells were immobilized on poly-l lysine coated slides. Imaging was then performed with a Leica SP5 confocal microscope equipped with a tunable white light laser (WLL) allowing for free choice of excitation wavelength (within a window ranging from 470 to 670 nm). AOBs (acusto-optical tunable filter) and spectral detection allowed additionally to freely choose appropriate detection windows. See [Table 1](#) for excitation emission conditions used.

Fluorescence emission was detected using a 63 $\times$ Plan-Apo oil immersion objective (NA 1.4) and newest generation hybrid (HyD) detectors with the pinhole closed to one airy unit. Cells were zoomed to obtain an effective pixel size of 50 to 80 nm fulfilling Nyquist criterion. For visualization purposes, helicene fluorophore emission is shown in purple, YFP emission in green and mitotracker deep red emission in cyan.
