Watersheds for Semi-Supervised Classification

Aditya Challa, Student Member, IEEE, Sravan Danda, Student Member, IEEE, B. S. Daya Sagar, Senior Member, IEEE and Laurent Najman, Senior Member, IEEE

Abstract—Watershed technique from mathematical morphology (MM) is one of the most widely used operators for image segmentation. Recently watersheds are adapted to edge weighted graphs, allowing for wider applicability. However, a few questions remain to be answered - (a) How do the boundaries of the watershed operator behave? (b) Which loss function does the watershed operator optimize? (c) How does watershed operator relate with existing ideas from machine learning. In this article, a framework is developed, which allows one to answer these questions. This is achieved by generalizing the maximum margin principle to maximum margin partition and proposing a generic solution. MORPHMORPHMEDIAN, resulting in the maximum margin principle. It is then shown that watersheds form a particular class of MORPHMEDIAN classifiers. Using the ensemble technique, watersheds are also extended to ensemble watersheds. These techniques are compared with relevant methods from literature and it is shown that watersheds perform better than SVM on some datasets, and ensemble watersheds usually outperform random forest classifiers.

Index Terms—Classification, Machine Learning, Mathematical Morphology, Maximum Margin Principle, Watersheds

I. INTRODUCTION

The problem of semi-supervised classification is stated as - Given a labelled dataset \{\{(x_i, y_i)\}\}, and a set of unlabelled data points \{\hat{x}_i\}, find the labels for unlabelled data points. There exist several possible approaches to solve the problem [1], [2]. One of the classic approaches is that of using Support Vector Machines (SVM) which relies on maximum margin classifier [3]. Several of these techniques depend on vector space structure of the underlying space. An alternate view can be proposed, based on lattices, by using ideas from Mathematical Morphology (MM). In this article, we analyze the use of watersheds from MM for semi-supervised classification.

Mathematical Morphology is a theory of non-linear operators using lattices, developed by G. Matheron and J. Serra in 1960s [4], [5]. One of the main operators in MM is that of watersheds. Originally developed for image segmentation, watersheds rely on either the drop of water principle or the principle of flooding to develop the algorithms for image segmentation (See watershed related chapters in [5] for detailed history). In [6], the authors extended the watershed principle to edge weighted graphs, and have established its links to the minimum spanning tree. The following algorithm describes a variant of the watershed algorithm proposed in [6] with arbitrary seeds, referred to as Minimum Spanning Forest (MSF)-Watershed in the rest of the article.

Input: A finite edge weighted graph \(G = (V, E, W)\), labelled seeds \(S \subseteq V\).

Output: Partition of \(V\)

1: Set \(E' = \emptyset\)
2: for \(e = (e_x, e_y)\) in sorted edge set \(E\) do
3: if both \(e_x\) and \(e_y\) are labelled then
4: pass
5: else
6: \(E' \leftarrow E' \cup (e_x, e_y)\)
7: Assign the same label to both \(e_x\) and \(e_y\).
8: end if
9: end for
10: return Partition generated by \(E'\).

Although the above algorithm is developed for the purpose of image segmentation, it can clearly be used for semi-supervised learning as well. This is achieved by taking the vertex set \(V = \{x_i\} \cup \{\hat{x}_i\}\), i.e. the union of labelled and unlabelled data points. Then, taking the seeds to be the labelled data points \(S = \{x_i\}\), and defining edge weights appropriately, one can use the watershed algorithm above for classification.

Watersheds have been used as a part of classification in images [7] and related algorithms have been used for data analysis as well. In [8], [9] the authors use the related image foresting transform [10] for supervised classification. In [11], the authors used watershed along with convolution neural networks (CNN) to obtain state-of-art results in CREMI challenge. Watersheds are also a part of the state of art image segmentation technique COB [12]. Broadly, watersheds fall under the group of semi-supervised classification algorithm, also referred to as few shot learning or transfer learning [13], [14]. See [15], [16] for recent advances in graph neural network approaches.

However, a few fundamental questions remain - (a) How do the boundaries of the watersheds behave when used as a classifier? (b) Which loss function does watershed optimize? (c) How does watershed relate with existing ideas from machine learning? To better understand the applicability of watersheds for learning, it is important to understand the answers to above questions.

The aim of this article is not to obtain the state-of-art results but to understand the behavior of watersheds when used as classifiers. The main contributions are - (i) We develop the framework generalizing maximum margin principle to sets equipped with dissimilarity measure. This leads to maximum margin partitions. (ii) We propose a simple classifier, MORPHMEDIAN, and prove that it always returns a maximum margin partition. (iii) It is then shown that watershed is a specific case of MORPHMEDIAN, and hence identifies the optimization problem solved by watersheds as classifier. (iv) Using the technique of ensembles, we extend the watersheds to Ensemble Watersheds. (v) MSF-Watershed, Ensemble Watersheds and related methods are compared on datasets from [2].
II. Maximum Margin Partition and morphMEDIAN

Recall that the technique of SVM is developed based on the principle of maximum margin. See [3] for details. From Fig. 1, SVM identifies the boundary such that the minimum margin for all points is maximized. We now generalize this principle. Assume that the set of points is given by $V$ and there exists a measure $\rho$ on $V$ such that $\rho(x, y)$ indicates the dissimilarity between $x$ and $y$. Note that $\rho$ need not be a metric, in particular the constraint of triangle inequality need not hold. One can extend this to subsets $X, Y \subseteq V$ as well by

$$\rho(X, Y) = \min_{x \in X, y \in Y} \rho(x, y)$$

(1)

With this framework, the classification problem can be restated as - Given $(V, \rho)$ and labelled sets $X_0, X_1 \subset V$ labelled 0 and 1 respectively, identify the partition $V = M_0 \cup M_1$ such that $X_0 \subset M_0$ and $X_1 \subset M_1$. Clearly $X_0 \cap X_1 = \emptyset$. For ease of exposition, only two classes are considered. All the definitions can be extended to a generic $k$ class problem as well.

In this case, drawing parallels from Fig. 1, one can define the margin between a point $x \in X_0$ and the boundary using $\rho(x, M_1)$. For the entire set $X_0$, the margin is then defined as $\rho(X_0, M_1)$. Similarly, the margin for $X_1$ is defined as $\rho(X_1, M_0)$. Hence, one can use the principle of maximum margin in generic spaces $(V, \rho)$ as well. This is defined below.

**Definition 1** (Maximum Margin Partition). Let $(V, \rho)$ be a set of points equipped with a dissimilarity measure. Let $X_0, X_1 \subset V$ denote the labelled subset of points with labels 0 and 1 respectively. A partition $V = M_0 \cup M_1$ with $X_i \subset M_i$ for $i = 0, 1$, is called the maximum margin partition if it maximizes

$$\min \{ \rho(X_0, M_1), \rho(X_1, M_0) \}$$

(2)

A natural question which arises from the above definition is - Can we characterize the maximum margin partitions? Consider the following definition of morphMEDIAN.

**Definition 2** (morphMEDIAN). Given the notation as above, a partition $V = M_0 \cup M_1$ is called a morphMEDIAN partition if

1) $x \in M_0$ if $\rho(X_0, x) < \rho(X_1, x)$.
2) $x \in M_1$ if $\rho(X_1, x) < \rho(X_0, x)$.

In simple words, a morphMEDIAN partition ensures that all points labelled 0 are closer to $X_0$ than $X_1$ and vice versa. Note that on the boundary, where $\rho(X_0, x) = \rho(X_1, x)$, the points can be labelled arbitrarily. The term morphMEDIAN is used since this definition is inspired from the definition of morphological median defined in [17]. See [18] for more details about morphological median. These definitions result in the following theorem, central to this section.

**Theorem 1.** Every morphMEDIAN partition is a maximum margin partition.

*Proof.* Firstly note that all morphMEDIAN partitions have the same value for margin, since the labelling of two morphMEDIAN partitions only differ in cases where $\rho(X_0, x) = \rho(X_1, x)$. Hence, it suffices to show that, given a maximum margin partition, one can construct a morphMEDIAN partition with greater or equal margin.

Let $M = M_0 \cup M_1$ be any maximum margin partition. If for all $x \in V$, the conditions in definition 2 hold, then $M$ is a morphMEDIAN partition and there is nothing to prove.

Otherwise, there exists a $z \in M_0$ such that $\rho(X_0, z) > \rho(X_1, z)$ or there exists a $z \in M_1$ such that $\rho(X_1, z) > \rho(X_0, z)$. If there exists a $z \in M_0$ such that $\rho(X_0, z) > \rho(X_1, z)$, then consider the following partition $M' = M_0 \cup M_1$ where

$$M_0' = M_0 \setminus z$$

$$M_1' = M_1 \cup z$$

Then, we have that $M'$ has a margin greater than or equal to $M$, as shown below.

$$\min \{ \rho(X_0, M_1'), \rho(X_1, M_0') \}$$

$$= \min \{ \rho(X_0, M_1), \rho(X_0, z), \rho(X_1, M_0) \}$$

$$\geq \min \{ \rho(X_0, M_1), \rho(X_1, z), \rho(X_1, M_0) \}$$

$$= \min \{ \rho(X_0, M_1), \rho(X_1, M_0) \}$$

Similarly, it follows that if there exists a $z \in M_1$ such that $\rho(X_1, z) > \rho(X_0, z)$, then, once again it is possible to construct a partition with greater or equal margin.

Repeat the above procedure until there does not exist $z$ which violates conditions in definition 2. The end of this procedure results in a morphMEDIAN partition. Hence proved. \hfill \Box

Note the similarity between morphMEDIAN and 1-Nearest Neighbor (1-NN) method for classification. The main difference between these two methods is that while 1-NN method classically considers a distance, morphMEDIAN generalizes this to any dissimilarity measure.

III. Watersheds for Semi-Supervised Classification

Definitions 1, 2 and theorem 1 allow us to characterize the behavior of watersheds as classifiers. Let $G = (V, E, W)$ be an edge weighted graph. $V$ is a set of vertices consists of both labelled and unlabelled points. $E \subset V \times V$ denotes the set of edges and $W : E \rightarrow \mathbb{R}^+$ denotes the weight (dissimilarity measure) assigned to each edge. Given the edge weighted graph, recall that watershed returns the partition given by algorithm described in section I.

Define, for $x, y \in V$,

$$\rho_{\text{max}}(x, y) = \min_{p \in \Pi(x, y)} \max_{e \in \pi} W(e)$$

(3)
where $\Pi(x, y)$ indicates the set of all paths between $x$ and $y$ in $G$. $\rho_{\text{max}}(., .)$ is also referred to as pass value [19]. Intuitively, it reflects the minimum height one has to reach to move from $x$ to $y$. We then have the following theorem.

**Theorem 2.** Given an edge weighted graph $G = (V, E, W)$, MSF-watershed returns a MOPHmedian partition with respect to $(V, \rho_{\text{max}})$. And hence, it gives a maximum margin partition in the space $(V, \rho_{\text{max}})$.

The proof of the above theorem follows from noting links between MSF-watershed and minimum spanning tree. For more details do refer to [20]. Theorem 2 characterizes the behavior of watersheds as a classifier. Fig. 2 denotes the boundaries obtained on toy datasets. Intuitively, the watershed partitions the graph by removing edges between points that are farthest apart. This implies that the boundary will be in between two classes with the least density of points. This is reflected in Fig. 2 as well.

One property of semi-supervised learning in general and, watershed classifiers in particular, is that both the train and test datasets are assumed to be known. Thus, classification of a new data point, would constitute adding the new point to the unlabelled dataset and running the algorithm again. However, thanks to the above properties of MSF-watershed, classification of a new data point only involves assigning the label of its nearest neighbor. This is consistent with running the algorithm again, since it is known that for any new data point, its 1-Nearest Neighbor is on the Minimum Spanning Tree. This is used to sketch the boundaries in Fig. 2.

**Other Classifiers in the Framework of Maximum Margin Partition**

The maximum margin partition framework discussed above also encompasses several known classifiers -

1) **IFT-SUM:** Instead of using $\rho_{\text{max}}(., .)$ as in (3), one can use the following measure

$$\rho_{\text{sum}}(x, y) = \min_{\pi \in \Pi(x, y)} \sum_{e \in \pi} W(e)$$ (4)

This is the classic shortest path distance, which can be efficiently calculated using the Image Foresting Transform (IFT) as described in [10]. This too can be used as a classifier as described in [8].

2) **Random Walk (RW):** An alternate approach to extending the local edge weights to $V \times V$ is by using the distances given by the Laplacian, one of which is the random walk distance as described in [22]. This induces a measure on $V \times V$. This is also referred to as label propagation [23].

3) **Power-Watershed (PW):** In [24], [25] the authors extend the MSF-watershed to use watersheds along with random walk giving good results for seeded image segmentation. It is shown in [24] that it is indeed a special case of MSF-watershed and hence also fits into the maximum margin framework.

**Ensemble Watersheds**

Observe that watersheds rely on the edge weights of the graph. In fact, once the graph $G$ has been chosen, apart from edge weights, there are no parameters for the watershed classifier. Thus, in situations where there exist a lot of redundant features, it is possible that a simple $L_2$ norm between the features would not reflect the dissimilarities well. This can be improved by considering watershed using subset of features and ensemble the results. Ensemble is a technique used widely in machine learning, in particular for random forests. See [1] for more details and references about ensemble techniques. We now adapt this to MSF-watersheds as well.

The algorithm for using ensemble watersheds is described below.

**Input:** Edge weighted graph $G = (V, E, W)$, labelled seeds $S \subset V$, $\tau_S :=$ Sampling percentage of seeds, $\tau_F :=$ Sampling percentage of features.

**Output:** Labelling of $V$

1: for $i \in \{1, 2, \cdots \text{number_iterations}\}$ do
2: Considering random subset of feature ($\tau_F$ percent), construct the new weight function $W'$.
3: Using $\tau_S$ percent of labelled data points, compute the watershed using the graph $G' = (V, E, W')$.
4: Compute estimate of accuracy using out-of-box samples, that is samples which are not used for labelling.
5: end for
6: Using estimates of accuracy as weights, compute the weighted average of the labels obtained by watersheds.
7: return Labels computed by taking the maximum of the average accuracies.

Note that the adjacency relation $E$ does not change across different estimators. This is because - either (a) adjacency relation is dictated by the domain, as is the case for images, in which case one need not change $E$ or (b) the adjacency relation is computed using $k$–nearest neighbor graphs, in which case, intuitively, the data spans a lower dimensional manifold in a higher dimensional space. The $k$–nearest neighbor graph constructed is expected to reflect the structure of this manifold. Hence, it makes sense to use the same graph with weights dictated by a subset of features. Also, in general, constructing the graph is a computationally expensive operation and using the same adjacency relation helps in implementing ensemble watersheds efficiently.

**Remark:** Although the technique of ensemble can be used with other techniques as well, the aim in this article is to understand MSF-watersheds and hence only ensemble of MSF-watersheds is considered.

**IV. Comparison with other classifiers**

In this section, we compare the results of the watershed and ensemble watershed classifiers with all the relevant clas-
ifiers - (i) Other techniques in the framework of maximum
margin partition - IFT-SUM, Random Walk (RW) and Power-
Watershed (PW). (ii) Support Vector Machines (SVM) since
the concept of maximum margin partitions developed here is
an extension of the maximum margin principle on which SVM
is based. In these experiments SVM is used with rbf kernel.
Also Transductive-SVM results are included for comparison.
(iii) 1-Nearest Neighbor (1-NN) due to the similarity between
MORPHMEDIAN and 1-NN methods. (iv) Random Forest
Classifier (RFC) since we consider the ensemble technique.
All implementations of these classifiers are taken from [21].

The collection datasets are taken from chapter 21 of [2],
since these datasets were designed to reflect several properties
of real datasets. The $k$–nearest neighbor graphs are then
constructed on these datasets which then are used as input
to the classifiers. The $k$ is chosen to be the least multiple of
10 so that the graph is connected. Also, each method is run
20 times for each datasets, taking random 20% of the data
as train data. The average and the standard deviations of the
accuracies are reported in table I. The code to generate the
results are available at [26].

In general, MSF-watershed performs better than SVM on
some datasets and worse on a few. Intuitively, MSF-watershed
relies heavily on the manifold structure of the data - The data
is assumed to be a lower dimensional manifold of a higher
dimensional space. Datasets $g241c$ and $g241n$ violate this
assumption and hence MSF-watershed does not return good
results. SVM on the other hand cannot predict highly non-
linear boundaries which is the case with COIL dataset.

Compared to Transductive SVM (TSVM), note that results of
TSVM and SVM are similar on almost all the datasets. Note
that TSVM does not generalize easily to multi-class
classification, due to which results for COIL (multiclass)
have not been generated. This is one of the open issues
with TSVM. By contrast, watersheds generalize trivially to
multiclass labels.

Ensemble watersheds in general work better than watersheds
to feature sampling. Ensemble watersheds also
outperform random forest classifier in most cases. However,
in cases where the entire feature set is a requirement for
identification of the class, other methods work better. This
is the case with USPS dataset, when ensemble techniques
such as random forest and ensemble watersheds have lower
performance compared to their non-ensemble versions such as
MSF-Watershed.

Intuitively, all classifiers based on edge weighted graphs
do not perform well when local distances do not reflect
the dissimilarities between the vertices. This is the case in high
dimensional datasets such as $g241c$ and $g241n$ where edge
weights do not reflect dissimilarities well. This can however
be mitigated by using other machine learning architectures for
estimating the weights, which is a part of the future work.

V. CONCLUSION AND FUTURE PERSPECTIVES

To summarize, a framework for using watersheds as
classifiers is developed. This is achieved by extending
the maximum margin principle to maximum margin partition.
MORPHMEDIAN is proposed, and it is proved that
MORPHMEDIAN always returns a maximum margin parti-
tion. It is also proved that watersheds are a specific case
of MORPHMEDIAN, and hence returns a maximum margin
partition. The technique is illustrated using toy datasets to
understand the behavior of the boundaries. We also illustrate how
watersheds can be combined with other ideas from machine
learning, by considering the ensemble technique. Adapting
the ensemble technique to watersheds is discussed in detail.
Further, these techniques are compared with other relevant
methods from literature on datasets from [2], showing that
ensemble watersheds generally outperform random forests.

The aim of this article is not to present state-of-art results,
but to understand the behavior of watersheds as classifiers bet-
ner. It is expected that this understanding would result in better
classifiers. For instance, one can infer from the framework that
obtaining good measures of local edge weights $E$ would result
in better classifiers. Hence, one can use techniques such as
neural networks to estimate the edge weights, which would
improve the accuracy of the classifiers. This is a topic of
further research.
