ABSTRACT

Acacia senegal gum (*Asen*) is a natural exudate of *Acacia* trees species largely used in food as well as other industries. This natural product appears as a continuum of molecular species which shows diverse sugar and protein composition, molar masses and charge density. The presence of larger macromolecules, or aggregates, has been demonstrated to have a great influence on the *Acacia* gum characteristics. The present work is designed to recover and characterize one protein-rich fraction presenting a high aggregate content. With this fraction we will open the door to future works with the aim to acquire a deeper knowledge about the origin and the role of the aggregates from *Asen* gum. Our methodology is based on the well-known ion exchange chromatography, using DEAE Sephacel gel as stationary phase. We have separated *Asen* into two different fractions (fraction IEC-F1 and fraction IEC-F2), being both of them confirmed as arabinogalactan-proteins (AGP) by Yariv detection. Fraction IEC-F1 has been thoroughly characterized (sugar and amino acid composition, molar mass distribution, weight-average molar mass, number-average molar mass, polydispersity index, intrinsic viscosity, radius of gyration, Mark-Houwink-Sakurada analysis, hydrodynamic radius, partial specific volume and partial specific adiabatic compressibility). From amino acid data, we have estimated that fraction IEC-F1 theoretically corresponds to about 70% of HIC-F3 and 30% of HIC-F2, respectively the second and the third fractions separated by hydrophobic interaction chromatography (HIC) and largely described in literature. The obtained information indicates that fraction IEC-F1 appears as a fraction highly rich in aggregates.

1. Introduction

Acacia gum, also known as gum Arabic, is a natural exudate of *Acacia* trees species, playing an important role in the plant defense (Nussinovitch, 2009). *Acacia* gum has been largely used from ancient times to the present day for different purposes such as food, pharmaceutical and other industries (reviewed by Sanchez et al., 2018). The most known *Acacia* gum is *Acacia senegal* (*Asen*) gum, which has been largely characterized in terms of composition (Idris, Williams, & Phillips, 1998; Lopez-Torrez, Nigen, Williams, Doco, & Sanchez, 2015; Renard, Lavenant-Gourgeon, Ralet, & Sanchez, 2006) and structure (Al-Assaf, Phillips, & Williams, 2005; Islam, Phillips, Slijvo, Snowden, & Williams, 1997; Verbeken, Dierckx, & Dewettinck, 2003). *Asen* gum are hyperbranched polysaccharides rich in arabinose and galactose mainly formed by chains of 3,6-linked β -D-Galp substituted in position 6 by

side chains of 3-linked α -L-Araf. Akiyama, Eda, and Kato (1984) were the first who suggested that *Acacia* gum was a kind of arabinogalactan-protein (AGP). AGP show some defining characteristics: their protein moiety is ranged around 1 and 10% of the total mass, while approximately their 90% are type II arabinogalactan chains having the ability to bind to β -glucosyl Yariv phenylglycoside (Lamport & Várnai, 2013; Tan et al., 2012). Besides, AGP are usually classified in hydroxyproline-rich superfamily of glycoproteins (Dickinson, 2003; Gleeson & Jermyn, 1979).

Acacia gum appears as a continuum of molecular species presenting diverse protein/sugar ratios, molar masses and charge densities (Renard et al., 2006). It is possible to fractionate *Acacia* gum through different procedures, hydrophobic interaction chromatography (HIC) being the most used technique (Osman, Menzies, Williams, Phillips, & Baldwin, 1993; Randall, Phillips, & Williams, 1989; Ray, Bird,

Iacobucci, & Clark, 1995; Renard et al., 2006). HIC gives three main AGP fractions: a major fraction (80–90% of total) historically named arabinogalactan-peptide (Fraction 1), which presents low protein content ($\sim 1\%$) and low mean molar mass ($2.8 \times 10^5 \text{ g mol}^{-1}$), another highly polydisperse arabinogalactan-protein complex (Fraction 2) of high molar mass ($1 \times 10^6 < M_w < 4 \times 10^6 \text{ g mol}^{-1}$) rich in protein ($\sim 10\%$) and another arabinogalactan-protein complex (1–2% of total gum) (Fraction 3) presenting the highest protein content ($\sim 25\%$) and polydispersity (Renard et al., 2006). These three AGP fractions were also called HIC–F1, HIC–F2 and HIC–F3 (Mejia Tamayo et al., 2018) based on the used separation technique and the elution order of the fractions, remaining consistent with the fact that all the three fractions are identified as AGP.

AGP complexity arises from their composition, conformation and polydispersity (Mejia Tamayo et al., 2018), but also to their capacity to self-aggregate (Al-Assaf, Sakata, McKenna, Aoki, & Phillips, 2009; Li et al., 2009). Several authors have found the existence of aggregates in *Acacia* gum (Dror, Cohen, & Yerushalmi-Rozen, 2006; Lopez-Torrez et al., 2015) or in AGP fractions from *Acacia* gum (Al-Assaf et al., 2009; Pickles et al., 2007; Renard, Garnier, Lapp, Schmitt, & Sanchez, 2012). Their differences towards aggregation in aqueous solution could be explained by their varying chemical composition, mainly their protein content and amino acid composition. Various works (Gashua, Williams, & Baldwin, 2016; Renard et al., 2012) depicted the presence of aggregated structures by transmission electron microscopy. Aggregate chains can render the identification of single AGP macromolecules very difficult (Renard et al., 2012). Main causes of the aggregation process could involve strong hydrophobic interactions between amino acid side chains in the polypeptide component of the gum (Renard et al., 2012) and/or intermolecular H-bonds between the saccharide portions (Mahendran, Williams, Phillips, Al-Assaf, & Baldwin, 2008). The protein-mediated aggregation processes appears as a key factor in the emulsifying properties (Castellani et al., 2010; Dumay, Picart, Regnault, & Thiebaud, 2006) and also in the intrinsic ability to stabilize complex coacervate (Sanchez & Renard, 2002). Mothe and Rao (1999) highlighted the shear-thinning behavior of *Acacia* gum solutions and assigned it to the presence of AGPs based micro-aggregates. Lopes, Andrade, Milas, and Rinaudo (1995) observed that the velocity of the particle sedimentation is affected by the type and size of the aggregates of welan gum. Manning and Bird (2015) found that aggregates could affect the *Acacia* gum fractionation through synthetic membranes. Aggregating *Acacia* gum through controlled Maillard reaction can improve its functional properties, the final product being called SUPER GUM™ (Al-Assaf, Phillips, Aoki, & Sasaki, 2007). Moreover, aggregates can hinder gums analysis and the consequent data interpretation (Qian, Cui, Wang, Wang, & Zhou, 2011) but also explain the observed discrepancies between the calculated and experimental R_H values in HIC–F3 fraction (Renard et al., 2014a). In view of the above discussion about the importance of aggregates, we consider that more extensive studies are needed on this key matter. Therefore, it would be interesting to find a separation approach to recover only one protein-rich fraction presenting a high aggregate content to unravel the origin and nature (structure, size, anisotropy) of aggregates, their strong link with protein moiety and their impact on physicochemical properties of these AGP-based aggregates. Based on the work of Osman et al. (1995) about the fractionation of the AGP-aggregate rich *Acacia* gum by ion exchange chromatography (IEC), we selected and adapted their procedure trying to obtain our desired high aggregate-content fraction. We have hence fractionated *Acacia* gum by IEC using DEAE Sephacel gel as stationary phase. Subsequently, we have characterized the obtained fractions, analysing their sugar, amino acid composition and structure, including molecular parameters such as the weight average (M_w) and number average (M_n) molar masses, the radius of gyration (R_g), the intrinsic viscosity ($[\eta]$) and the polydispersity index (M_w/M_n) to achieve a deeper knowledge of them. In summary, this work will provide and characterize one aggregate-rich fraction from *Acacia senegal* gum which

will help for understanding the solution properties of the individual macromolecules families and their aggregates in solution.

2. Material and methods

2.1. Material

Acacia gum type from *Acacia senegal* trees located in Sudan (Lot: OF152413) was provided by ALLAND & ROBERT Company – Natural and organic gums (Port Mort, France).

2.2. Preparation of *Acacia senegal* gum (Asen) dispersions

Asen dispersions were prepared by weight (wt %). Known amounts of *Asen* powder (650 g, corresponding to 581 g in dry terms) were dispersed in water (6500 mL) and gently stirred for 24 h at room temperature (20 °C). The pH of dispersions was subsequently adjusted at 3.5 using HCl 1 N, HCl 0.1 N, or NaOH 0.5 N solutions.

2.3. Ion exchange chromatography (IEC)

IEC separation was performed at room temperature on DEAE Sephacel (Sigma Aldrich, St. Louis, Mo) column (54 × 20 cm). The column was firstly equilibrated with degassed water. Dissolved *Asen* was loaded and eluted by water (around 10 L) at a flow rate of 40 mL min^{−1} to obtain a first fraction called IEC-F1. Subsequently, a gradient was performed during 5 h starting with water and finishing with 2 M NaCl (flow rate: 20 mL min^{−1}). A second fraction termed IEC-F2 was then obtained, eluting with 2 M NaCl (around 20 L), at a flow rate of 20 mL min^{−1}. The volume employed during the gradient phase was added to the 20 L corresponding to the fraction IEC-F2. The two fractions obtained were separately heated (50 °C) and concentrated using a cross flow filtration system (ÅKTA flux, GE Healthcare) (flow: 4 L min^{−1}; TMP -corresponding to feed pressure – Retentate pressure: 15 psi; column: UFP-30-C-4x2MA, 30 kg mol^{−1}). Fractions IEC-F1 and IEC-F2 were afterward diafiltered against 10 volume of water in the same conditions to eliminate salts. The fractions were spray-dried using a B-290 Mini Spray Dryer (BUCHI™).

2.4. Yariv detection

β -glucosyl Yariv reagent (β -D-Glc Yariv reagent) has been largely used in the study of AGP (Osman et al., 1993; Paulsen, Craik, Dunstan, Stone, & Bacic, 2014; Sims & Furneaux, 2003). Petri dishes containing 1% agarose gel in 10 mM Tris buffer, pH 7.3, with 0.9% NaCl and 1 mM CaCl₂ were used. β -D-Glucosyl Yariv reagent (Biosupplies, Victoria, Australia; 40 μ L, 1 mg mL^{−1}) was delivered to a central well. Fractions IEC-F1 and IEC-F2 were placed in equidistant peripheral wells and petri dishes were left overnight at 25 °C. Arabinogalactan from larch wood (Sigma Aldrich, St. Louis, Mo) was used as negative control.

2.5. Sugar composition as trimethylsilyl derivatives

According to Doco, O'Neill, and Pellerin (2001), the neutral and acidic sugar composition was determined after solvolysis with anhydrous MeOH containing 0.5 M HCl (80 °C, 16 h) of their per-O-trimethylsilylated methyl glycoside derivatives, by gas chromatography (GC) on a Shimadzu GCMS-QP2010SE gas chromatograph (Shimadzu, Kyoto, Japan) connected to a flame ionization detector at 250 °C, using a fused silica DB-1 capillary column (30 m × 0.25 mm i.d., 0.25 μ m film) (temperature programming 120–200 °C at 1.5 °C/min), with hydrogen as the carrier gas. The separation of the TMS derivatives was previously described (Apolinar-Valiente et al., 2014).

2.6. Amino acid analysis

Total amino acids were analysed with a Biochrom 30 analyser (BIOCHROM 30, Cambridge, UK). Amino acid composition of samples was determined after acid hydrolysis (6 N HCl) and heating at 110 °C for 24 h. The excess of acid was eliminated and hydrolysed samples were analysed by liquid chromatography on an ion-exchange column (Ultra-pac-8 lithium form; Amersham Pharmacia Biotech, Piscataway). Lithium citrate (0.2 M, pH 2.2) was used as eluent and norleucine as internal standard.

2.7. Molar mass distribution analysis, static and dynamic molecular parameters

Asen, fraction IEC-F1 and fraction IEC-F2 were analysed by size exclusion chromatography (SEC). The SEC line was constituted, depending on the analysis, by an OHPAK SB-G guard pre-column followed by one column (OHPAK SB 805 HQ, Shodex) for fraction IEC-F1, and four columns (OHPAK SB 803, 804, 805 and 806 HQ, Shodex) for fraction IEC-F2 and *Asen*. Selection of the appropriate type of columns for each sample was done after several testing (data not shown). The flow carrier (0.1 M LiNO₃) was filtered (0.1 µm filter, Millipore) and pumped at 1 mL min⁻¹. The samples were dissolved in filtered Milli-Q water (1 mg mL⁻¹), stirred gently (24 h), centrifuged (10 000 rpm, 10 min) and injected (10 µL for fraction IEC-F1 and 75 µL for fraction IEC-F2 and *Asen*). Weight average (M_w) and number average (M_n) molar masses were determined using a multi-angle laser light scattering (MALLS) (DAWN-Heleos II from Wyatt, CA, USA), an on-line differential viscometer (VISCOSTAR II, Wyatt, CA, USA), a UV-VIS detector (280 nm) (SPD-20A, Shimadzu, Japan) and a differential refractometer (Optilab T-Rex, Wyatt, Santa Barbara, CA, USA). The refractive index increment values (dn/dc) were determined as 0.155, 0.158 and 0.155 mL g⁻¹ for *Asen*, IEC-F1 and IEC-F2, respectively. The collected data were analysed using the Astra 6.1.84 software package.

2.8. Density and sound velocity

Density and sound velocity were determined using a DSA 5000M sonodensimeter (Anton Paar, France). Dispersions were prepared and dialyzed overnight against 0.1 M sodium acetate buffer (pH 5). Measurements were performed in degassed dispersions (15 min) to remove dissolved air and triplicated.

2.9. Dynamic light scattering (DLS)

The translational diffusion coefficient (D_T) was determined using a NICOMP nano Z (Z3000) equipment (PSS, USA). Dispersions were prepared at 5 g L⁻¹ in deionized water (18 mΩ, pH 5, 25 °C) and filtrated (0.22 µm, VWR International, USA) to eliminate large aggregates. Measurements were performed at 25 °C and in triplicate. Data were analysed using the NICOMP 2.0 software. The hydrodynamic radius (R_H) was obtained from the autocorrelation curve, which was fitted using the cumulant method. In addition, the NICOMP software allowed the qualitative discrimination of up to three molecule populations using the non-linear least squares method.

3. Results and discussion

The objective of this work is to fractionate *Asen* gum through a separation method enabling to recover one single protein-rich fraction with high aggregate content. First, we will present the sugars and amino acid composition of the starting *Asen*, as well as its structural characteristics analyses. Secondly, we will show the yield of the aggregates recuperation and Yariv reagent precipitation after our fractionation of *Asen* by IEC. Finally, the sugars and amino acid composition, the structural analysis and some characteristics such as the number of

charges, the hydrophobicity index and the hydrodynamic radius of the obtained fractions will be presented, focusing mainly on the high aggregate-content fraction.

3.1. The starting *Asen*

To present our starting *Asen* properly, we show at first, its sugar composition (Table 1) and its total content of amino acids (Table 2). Subsequently, we give as determined by MALLS, differential refractometer and viscometer, the HPSEC-MALLS chromatogram (Fig. 1), as well as the data about molar mass distribution and static (M_w , M_n and R_g) and dynamic ($[\eta]$) molecular parameters of *Asen* (Table 3).

3.1.1. Sugars and amino acid composition of *Asen*

The most abundant sugar components are galactose (38.5%) and

Table 2

Amino acid composition (%) and total amino acid content (mg amino acid g⁻¹ of sample) of *Acacia senegal* gum (*Asen*), as well as fractions HIC-F2, HIC-F3, IEC-F1T, IEC-F1 and IEC-F2.

Amino Acid	Asen	Fraction HIC-F2 ^a	Fraction HIC-F3 ^a	Fraction IEC-F1T ^b	Fraction IEC-F1	Fraction IEC-F2

^a From Mejia Tamayo et al. (2018), in Supplementary material.

^b Calculated considering that IEC-F1 is composed by 70% of HIC-F3 and 30% of HIC-F2.

^c The acid hydrolysis used in amino acid composition analysis converts asparagine to aspartic acid and glutamine to glutamic acid, or destroys some amino acids such as tryptophan, so these residues are not measured and not reported in the table.

Fig. 1. Size exclusion chromatograms showing the elution profiles monitored by refractometer: relative refractive index (thick line) and molar mass ($\text{g}\cdot\text{mol}^{-1}$; thin line) of *Acacia senegal* gum (*Asen*, egi10HHMDRSV0P) as well as of fractions IEC-F1 (egi10F1PN563G0) and IEC-F2 (egi10M13FFB2KT).

arabinose (29.8%) (Table 1) being in agreement with its AGP nature. The calculated Ara/Gal molar ratio for *Asen* is 0.8. Likewise, our starting gum presents values of 12.8% for rhamnose, 1.0% for 4-O-methyl glucuronic acid and 17.9% for glucuronic acid. All these values are consistent with those found in literature (Gashua et al., 2016; Idris et al., 1998; Lopez-Torrez et al., 2015; Nie et al., 2013; Renard et al., 2006).

As well, regarding the amino acid composition (Table 2), hydroxyproline is the most abundant amino acid found in *Asen*, serine being the second largest amino acid (Gashua, Williams, Yadav, & Baldwin, 2015; Lopez-Torrez et al., 2015; Mahendran et al., 2008; Renard et al., 2006). This is in accordance with the inclusion of AGP in the group of the HRGPs (hydroxyproline-rich glycoproteins), which is a generic term covering all molecules that are rich in hydroxyproline/proline (generally $\geq 5\%$) (Sommer-Knudsen, Bacic, & Clarke, 1998). Other amino acids which present high percentages are leucine, proline and threonine, whereas alanine, arginine, isoleucine and tyrosine appear as minor amino acids. Focusing on the total content of amino acids, *Asen*

shows 20 mg g^{-1} of sample, this is in agreement with values observed in gum samples by many authors (Osman et al., 1993; Randall et al., 1989).

3.1.2. Size exclusion chromatograms and M_w distribution analysis, static and dynamic molecular parameters of *Asen*

The *Asen* chromatogram obtained by refractometry presents two macromolecular populations with different proportions (Fig. 1). The main population is eluted between 28 and 35 min (RI), being composed of low M_w AGP. A second minor population also appears between 24 and 28 min, corresponding to high M_w AGP. Several authors have obtained similar profiles (Renard et al., 2006; Gashua et al., 2015; Lopez-Torrez et al., 2015) attributing the main peak to HIC-F1 along with a certain amount of HIC-F2, whereas the smallest peak mainly consists of most HIC-F2 as well as HIC-F3 and corresponds to aggregate population (Randall et al., 1989; Renard et al., 2006). Fig. 1 also presents the M_w distribution (MWD) of *Asen*, being similar to this given in previous studies (Gashua et al., 2015; Lopez-Torrez et al., 2015; Renard et al., 2006).

Concerning the distribution analysis of *Asen* (Table 3), three different ranges have been selected in order to ensure a good comparison of the percentages of macromolecules with low (range 1: between 1×10^3 and $5 \times 10^5 \text{ g mol}^{-1}$), intermediate (range 2: between 5×10^5 and $1 \times 10^6 \text{ g mol}^{-1}$) and high (range 3: between 1×10^6 and $1 \times 10^7 \text{ g mol}^{-1}$) molar masses. *Asen* shows statistically higher values in the range 1 (67.5%) as compared to range 2 (17.0%) and range 3 (15.4%). The M_w and M_n values for *Asen* are respectively $6.5 \times 10^5 \text{ g mol}^{-1}$ and $3.0 \times 10^5 \text{ g mol}^{-1}$, which is comparable with literature data (Gashua et al., 2015; Idris et al., 1998; Lopez-Torrez et al., 2015). In addition to molar masses, the radius of gyration (R_g) is a useful parameter to characterize the polymer structure. This measure of molecular size was only taken into account for values above 10 nm due to the sensitivity limit of the MALLS detector. Using this criterion, 63% of macromolecules were considered, implying that this parameter must be carefully interpreted. The obtained value for *Acacia* gum (29 nm) is in agreement with that observed by Lopez-Torrez et al. (2015). However Sanchez, Renard, Robert, Schmitt, and Lefebvre (2002) and Gashua et al. (2015) found lower values for this parameter, which may be related to varying percentages of macromolecules considered to calculate this parameter. This fact could also be linked to the different origins of *Acacia* gum and/or the age of trees (Gashua et al., 2015; Idris et al., 1998). In this regard, the characterization of *Acacia* gum harvested on trees of different ages showed the gain in the proportion of aggregates in solution when the trees grow older up to about 15 years.

The intrinsic viscosity ($[\eta]$) is directly linked to the hydrodynamic volume then related to the gum molar mass (Mudgil, Barak, & Khatkar, 2012; Robinson, Ross-Murphy, & Morris, 1982) and the hydration

Table 3

Cumulative percentage ranges (%) and molecular parameters of *Acacia senegal* gum (*Asen*) and fractions HIC-F2, HIC-F3, IEC-F1T, IEC-F1 and IEC-F2, determined by SEC-MALLS, differential refractometer and viscometer.

Ranges and Molecular parameters	<i>Asen</i>	Fraction HIC-F2	Fraction HIC-F3	Fraction IEC-F1T ^a	Fraction IEC-F1	Fraction IEC-F2

^c Nc: not calculated.

^d Some of the data shown in Table 3 were not described in Material and Methods section. We used these data for purpose of comparison and simplification.

Fig. 2. Mark-Houwink-Sakurada (MHS) plot showing the intrinsic viscosity ($[\eta]$; $\text{mL}\cdot\text{g}^{-1}$) as a function of molar mass (M_w ; $\text{g}\cdot\text{mol}^{-1}$) for *Asen* (Fig. A) and fractions IEC-F1 (Fig. B) and IEC-F2 (Fig. C).

status and conformation of macromolecules. This in turn is linked to the primary sugars and amino acid composition and the structure of AGP (topological complexity, surface roughness, presence of grooves, etc.). The $[\eta]$ is widely used to study the structural properties of biopolymers and the effects of the solvent environment on the stability of polymers in solution (Sibaja-Hernández, Román-Guerrero, Sepúlveda-Jiménez, & Rodríguez-Monroy, 2015). The $[\eta]$ value for *Asen* is $30 \text{ mL}\cdot\text{g}^{-1}$, which is within the defined range (between 15 and $31 \text{ mL}\cdot\text{g}^{-1}$) reported in literature (Bai et al., 2017; Karamalla, Siddig, & Osman, 1998; Lopez-Torrez et al., 2015; Sanchez et al., 2002; Vandeveld & Fenyo, 1985). These low values are a known characteristic of hyperbranched polymers (Aerts, 1998; Yan, Gao, & Frey, 2011).

Fig. 2 shows the Mark-Houwink-Sakurada (MHS) analysis, relating the intrinsic viscosity $[\eta]$ to M_w . The relation between these two

parameters is a relationship whereby $[\eta] = K\alpha M_w^\alpha$, being $K\alpha$ a constant and α exponent value is called hydrodynamic coefficient (Burchard, 1999). The hydrodynamic coefficient is presented by plot slopes, providing deeper information about conformation and structure of macromolecules. This hydrodynamic coefficient theoretically varies from 0 (sphere) to 1.8 (rod) with values of 0.3–0.5 for hyperbranched polysaccharides (Callaghan & Lelievre, 1985; Lelievre, Lewis, & Marsden, 1986; Millard, Dintzis, Willett, & Klavons, 1997; Rolland-Sabaté, Mendez-Montealvo, Colonna, & Planchot, 2008) and values of 0.5–0.8 for flexible polymers depending on the solvent quality (Ross-Murphy, 1994). It can be observed that MHS plot from *Asen* cannot be described by one slope but by three, which is in total accordance with data reported by Lopez-Torrez et al. (2015). The α values are lower than 0.5 for the first part (low M_w ranges) and the last part (high M_w ranges) of *Asen*. According to the above mentioned works, all of them correspond to hyperbranched structures. In the same vein, Li, Lu, An, and Wu (2013) reported similar results with synthetic hyperbranched polymers. Besides, the molecules with α values between 0.3 and 0.4 would theoretically correspond to spheroid structure (Burchard, 1999). On the other hand, α exponents for intermediate parts of *Asen* show values between 0.6 and 0.7, which are suggested as linear random coil conformation. However, these high α values seems to disagree with the largely proved fact that *Acacia* gum macromolecules are hyperbranched polymers. It is important to highlight that the molecular polydispersity and the effect of chain branching requires a careful interpretation for polymers having complex hydrodynamics (Ross-Murphy, 1994). Anisotropy, temperature, polymer-solvent interactions and polydispersity influence α exponent values. Moreover, Lopez-Torrez et al. (2015) found similar trends studying *Asen* gum, suggesting that the intermediate range of M_w might imply larger anisotropy or smaller chain density than the other two ranges (low and high M_w range). Concerning the average values, α exponent value of *Asen* (0.52) is similar to those previously obtained, which ranged between 0.51 and 0.55 (listed by Lopez-Torrez et al., 2015).

3.2. Fractionation of *Asen* by IEC: yield of the aggregates recuperation and Yariv reagent precipitation

In the light of all the data shown in previous sections, we can confirm that our starting *Asen* gum corresponds to a conventional and largely referenced *Asen* gum. Therefore, our gum is a good starting point to achieve our prime objective, that is to say, to obtain a fraction with high content of aggregates from *Asen*. Consequently, we have completed the IEC fractionation. 581 g (dry matter) of *Asen* were loaded on IEC column. After all the steps of fractionation, 25 g (4.3% of initial gum) of fraction IEC-F1 and 496 g (85.4% of initial gum) of fraction IEC-F2 were recovered. In our opinion, the total yield (89.7% of initial gum) can be considered as satisfactory, because losses can occur during the fractionation, concentration step, diafiltration and spray-drying procedures. The total recovery yield of aggregates might be optimized, but this is not our primary objective.

Yariv's reagent precipitates both fractions IEC-F1 and IEC-F2 (Fig. 3). This fact corroborates as expected that they belong to AGP family. In the same line of our results, two fractions from gum separated by preparative GPC (Qi, Fong, & Lampert, 1991) were found to interact with Yariv reagent, as well as four fractions separated by HIC (Osman et al., 1993).

3.3. Fractions IEC-F1 and IEC-F2: composition and structure

Given that our objective is a fraction with high content of aggregates, we will mainly focus our discussion on the results of the fraction IEC-F1. The data obtained from IEC-F2 are also shown in the different Tables and Figures, being similar to those from *Asen*.

Fig. 3. Yariv's reagent analysis for fraction IEC-F1 (1), fraction IEC-F2 (2), Asen (3) and AGP from larch wood (4).

3.3.1. Sugars and amino acid composition of fractions IEC-F1 and IEC-F2

Table 1 shows the neutral sugars and uronic acid composition of the IEC-F1 fraction. As above mentioned, arabinose and galactose appears as major component. Fraction IEC-F1 shows high molar percentage of arabinose (36%) and low percentage of galactose (34%). These results are in the line of those previously obtained by Randall et al. (1989) and Renard et al. (2006). We find a smaller content of glucuronic acid groups in the case of fraction IEC-F1, which may induce lower electrostatic repulsions and, hence, a higher tendency to aggregation compared to the other two samples studied (Asen and fraction IEC-F2). It has been observed that, studying the emulsifying properties of *Acacia* gum, the polar heads contain a negative charge derived from the glucuronic acids, which creates a barrier of repulsive forces preventing oil droplets aggregation (Nieto, 2014). Ferreira, Freitas, and Teixeira (2003) found that certain carbohydrate, including glucuronic acid, interfered with the self-aggregation of legume seed storage proteins process. Randall et al. (1989) and Renard et al. (2006) also found lower uronic acids amount in HIC-F3 fraction in comparison to fraction HIC-F1 of the *Acacia* gum.

The amino acid composition and total amino acid content of fraction IEC-F1 are presented in Table 2. As expected, hydroxyproline appears as the largest amino acid contained in fraction IEC-F1, followed by serine. Other amino acids which present high percentages are leucine and histidine. If we focus on the total content of amino acids, fraction IEC-F1 presents a large value ($115 \text{ mg amino acid} \cdot \text{g}^{-1}$ of sample). Several authors have reported different content of amino acid depending on the obtained fraction, whatever the procedure of separation employed (Osman et al., 1995; Qi et al., 1991; Randall et al., 1989). Differences of protein content and amino acids composition have been suggested as the cause of the varying aggregation behavior of classical HIC-obtained fractions. The high protein amount as well as the greater percentage of hydrophobic amino-acids in HIC-F3 fraction would hence justify the highest sensitivity of macromolecules from this fraction towards self-assembly and subsequent aggregation in aqueous solution (reviewed by Sanchez et al., 2018). From that, and keeping in mind its high total content of amino acids, it seems logical to conclude that our fraction IEC-F1 would show a high trend to form aggregates, corresponding to our objective.

From the amino acid composition and content, it can be easily deduced that, as expected, high aggregate-content IEC-F1 fraction is

mainly composed by classical HIC-F2 and HIC-F3 fractions. We have roughly estimated, using the corresponding data reported in Supplementary material by Mejia Tamayo et al. (2018) on HIC-F2 and HIC-F3 fractions and testing different percentages, that IEC-F1 is formed by around 70% of fraction HIC-F3 and 30% of fraction HIC-F2. Using these estimated percentages, we calculate the composition of a theoretical fraction named IEC-F1T, whose planned composition data are also shown in Tables 1 and 2. Regarding Table 2, we can observe that the amino acids composition and total content of experimental IEC-F1 fraction corresponds reasonably to our theoretical IEC-F1T fraction. Concerning Table 1, the neutral sugars and uronic acids composition of IEC-F1 fraction matches a little less with our calculated IEC-F1T fraction, although the mentioned corresponding tendency continues to be observed. Moreover, it should be noted that our experimental IEC-F1 fraction would also present a certain percentage of fraction HIC-F1, although it has been not taken into account with a view to simplify the theoretical calculations.

3.3.2. Size exclusion chromatograms and M_w distribution of fractions IEC-F1 and IEC-F2

Regarding the chromatogram of fraction IEC-F1 (Fig. 1, one Shodex column used), the elution time from its major population (RI signal) corresponds to values between 5 and 9 min, and presents high M_w . This population is classically identified as HIC-F2 and HIC-F3 fractions (Mejia Tamayo et al., 2018; Randall et al., 1989; Renard et al., 2006), the major components of IEC-F1 aggregates. A minor and hardly separable population can also be deduced as a shoulder between 9 and 11 min, showing low M_w . Concerning the MWD of fraction IEC-F1, the fact that we have used only one Shodex column to reduce anomalous diffusion effects of high M_w hyperbranched molecules explains the different MWD slope. In any case, the MWD curve of fraction IEC-F1 is located above these of fraction IEC-F2 and Asen along almost all the elution time. Concerning molar mass distribution of IEC-F1 aggregates, it shows high value (97.4%) in range 3, whereas no or low (2.5%) molar mass appears in ranges 1 and 2 (Table 3). Looking at all these results, they are in coherence with the fact that, as expected, we get a part of the AGP with high M_w from Asen with our IEC procedure, corresponding to fraction IEC-F1. Moreover, we have obtained a significant difference between the molar mass distribution of IEC-F1 aggregates and those calculated for IEC-F1T using the constituent assigned ratio [70% of HIC-F3 and 30% of HIC-F2] (Table 3): range 1: 13.6%, range 2: 25.7% and range 3: 60.7%. These great differences, particularly in the case of range 3, can be attributed to the gain of aggregates.

From the whole data shown above, we can conclude that the charge plays the most important role in our IEC separation, although it can also be important to consider the accessibility of the charged molecules to the gel. In this regard, we think that the hydrodynamic volume of the macromolecules also plays a part in our separation. The possibility of a steric disability using anion-exchange chromatography to fractionate *Acacia* gum was previously reported by Osman et al. (1995).

3.3.3. Static and dynamic molecular parameters of fractions IEC-F1 and IEC-F2

Table 3 shows the static and dynamic parameters of fractions IEC-F1 and IEC-F2. From the data reported by Mejia Tamayo et al. (2018) we have also calculated the M_w and M_n values of our theoretical IEC-F1T fraction (Table 3), again using the constituent assigned ratio [70% of HIC-F3 and 30% of HIC-F2]. Therefore, we have obtained an enormous difference between the calculated M_w ($1.6 \times 10^6 \text{ g mol}^{-1}$) and M_n ($9.6 \times 10^5 \text{ g mol}^{-1}$) values of IEC-F1T and the experimental data of IEC-F1 (M_w : $3.1 \times 10^6 \text{ g mol}^{-1}$ and M_n : $2.5 \times 10^6 \text{ g mol}^{-1}$). These great differences between theoretical and experimental results can be explained by the presence of aggregates, whose high level would increase the M_w and M_n values. From these values, the polydispersity value (M_w/M_n) of the fraction IEC-F1 shows logically lower value (1.2) compared with the fraction IEC-F1T (1.7).

It must be remarked that, as previously mentioned, the radius of gyration (R_g) of each sample was only taken into account for values above 10 nm. Using this criterion, 100% of macromolecules from fraction IEC-F1 are considered, resulting in a very high R_g value (44 nm). This result is logical knowing that, as calculated, fraction IEC-F1 is formed by 70% of HIC-F3 and that Renard et al. (2006) reported that HIC-F3 fraction showed higher R_g values compared to predominant HIC-F1 fraction. We have not calculated the R_g values of IEC-F1T fraction because of the difficulties involved in used percentage of macromolecules used to this calculation. However, it can be valuable to note that we previously found R_g values of 29.4 nm and 33.3 nm in, respectively, fraction HIC-F2 and HIC-F3 (Table 3). Therefore, even without estimating the precise R_g value of IEC-F1T, we can deduce an obvious difference between theoretical and experimental values for this parameter. Al-Assaf et al. (2009) observed that an increase of R_g from 33 to 73 nm was caused by aggregation involving hydrophobic association of the proteinaceous components from *Acacia* gum molecules after heating treatment. The same authors reported an increase of R_g from 25 to 67 nm after irradiation treatment of *Acacia* gum, explaining this aggregation through C–C covalent bonds between the carbohydrate moieties. Therefore, high values of R_g parameters could be also linked to aggregation phenomenon.

The intrinsic viscosity ($[\eta]$) (Table 3) of high aggregate-content IEC-F1 fraction appears as a very high (87.8 mL g^{-1}) value. This parameter in *Acacia* gum has been suggested as strongly linked to the protein content (Chikamai, Banks, Anderson, & Weiping, 1996) as well as to the molar mass. Al-Assaf et al. (2007) associated a rise of 20-fold in fluid viscosity with an increase of molar mass from 4.24×10^5 to $14.5 \times 10^5 \text{ g mol}^{-1}$ during a maturation procedure of *Asen* gums. The $[\eta]$ value (Table 3) and the amino acid total content (Table 2) of fraction IEC-F1 are in perfect coherence with these two remarks, which can be explained by the fact that protein-rich macromolecules in *Acacia* gum display generally high M_w . Moreover, we have calculated the $[\eta]$ value of IEC-F1T fraction (57.6 mL g^{-1}) through the constituent assigned ratio [70% of HIC-F3 and 30% of HIC-F2], knowing that HIC-F2 and HIC-F3 presents values of 64.3 and 54.7 mL g^{-1} (Table 3). The great difference of $[\eta]$ values between fraction IEC-F1 and fraction IEC-F1T might be attributed to the aggregates. In this line, Li et al. (2009) reported that the viscosity reduces synchronously with dissociation of aggregates.

The results of Mark-Houwink-Sakurada (MHS) analysis for fractions IEC-F1 and IEC-F2 are shown in Fig. 2. MHS plot from fraction IEC-F1 can be described by one single slope. The α value is lower than 0.5 for fraction IEC-F1, which would correspond to hyperbranched structures. Li et al. (2013) reported the same conclusions using synthetic hyperbranched polymers. As said before, the macromolecules showing α values between 0.3 and 0.4 would be theoretically identified as spheroid structures (Burchard, 1999). Renard, Lavenant-Gourgeon, Lapp, Nigen, and Sanchez (2014b) found that fraction HIC-F3 showed a hydrodynamic coefficient value of 0.45, which is close to our value for fraction IEC-F1 (0.35), but even higher than the latter. The explanation of the observed lower α value of fraction IEC-F1 would correspond to the presence of aggregates, as shown by Bello-Pérez, Roger, Colonna, and Paredes-López (1998), which would perfectly conform to our principal aim.

As shown by Lopez-Torrez et al. (2015) in *Asen*, Fig. 4 compares theoretical calculations of objects with increasing anisotropy (spheres, oblate and prolate ellipsoids and rods) with our obtained results. Fraction IEC-F1 shows prolate ellipsoid conformation, whereas fraction IEC-F2 contains molecules with more oblate ellipsoid-like conformation at low M_w and more anisotropic conformations at larger M_w . The aggregates in fraction IEC-F1 could hence influences on its conformation. In this vein, Callaghan, Lelievre, and Lewis (1987) found that wheat amylopectin dispersed in DMSO solutions corresponded to an oblate ellipsoid conformation, whereas the same molecules dispersed in water aggregated to yield a more spherical shape.

Fig. 4. Radius of gyration (R_g) as a function of hydrodynamic radius (R_h) for fractions IEC-F1 (egi10F1PN563G0) and IEC-F2 (egi10M13FFB2KT). Black lines represent theoretical calculations for objects with increasing anisotropy (from Lopez-Torrez et al., 2015).

3.3.4. Number of charges and hydrophobicity index of fractions IEC-F1 and IEC-F2

The contribution of the polysaccharide and protein moiety of IEC fractions to basic molecular characteristics has been calculated by combining the biochemical and structural properties (Table 4). The average M_w of the polysaccharide and protein part have been estimated considering the sugar (Table 1) and amino acid (Table 2) composition of each sample. The amount of free OH in the polysaccharide part was calculated through the linkage of the neutral sugars and the number of possible interacting sites of the protein portion, bearing in mind the interacting sites of each amino acid. Finally the hydrophobicity was

Table 4

Basic molecular characteristics of *Acacia senegal* gum (*Asen*), as well as fractions IEC-F1 and IEC-F2.

	<i>Asen</i>	Fraction IEC-F1	Fraction IEC-F2
M_w (g mol^{-1})	645500	3100000	529900
Sugars (%) ^a	94.71	88.21	92.56

Potential number of charged and polar interacting sites (protein moiety)	92	1915	63
Potential number of non-polar interacting sites (protein moiety)	16	329	12
Hydrophobicity index	−1.18	−1.39	−1.15

^a Sugars percentage was determined by the difference of proteins and minerals from 100% of sample.

determined using the amino acid hydrophobicity scale proposed by Zhu et al. (2016).

From the number of polar and charged interacting sites of the polysaccharide portion, the number of charges contributed by fraction IEC-F1 is much higher than fraction IEC-F2 (49210 and 9395, respectively), which may be explained by their corresponding content of sugar residues (16123 and 3012, respectively) (Table 4). Regarding the protein part, the number of charges contributed by fraction IEC-F1 is also much higher (1915) than fraction IEC-F2 (63), being explained by their corresponding content of amino acid residues (2755 and 66, respectively) (Table 4).

Concerning the hydrophobicity index, fraction IEC-F1 appears as more hydrophobic (-1.39) than fraction IEC-F2 (-1.15), which seems coherent bearing in mind the number of non-polar interacting sites (329 and 12, respectively). Therefore, although our IEC fractionation methodology separates the macromolecular fractions mainly in terms of hydrodynamic volume and number of charge sites, the occurrence of hydrophobic interactions could also be suggested.

3.3.5. Hydrodynamic radius of fractions IEC-F1 and IEC-F2

The hydrodynamic radius (R_H) of *Asen* and its fractions IEC-F1 and IEC-F2 was calculated from the translational diffusion coefficient (D_T), which was obtained from the autocorrelation curves. The autocorrelation curves of *Asen*, IEC-F1 and IEC-F2 obtained from measures of a 5 g.L^{-1} prepared in a salt-free dispersion are presented in Fig. 5. Small molecules tend to move faster than large molecules. Thus, they have a bigger impact on the fluctuation of the intensity signal. Therefore, its autocorrelation curve presents a faster decay. The results show a clear influence of the presence of supramolecular assemblies in the IEC-F1 fraction, since for the same decay time a higher intensity of the signal was measured. Therefore, our results are in accordance with the theory. In addition, the NICOMP analysis allowed the qualitative discrimination of up to three molecule populations. These results together with the

Table 5

Hydrodynamic radius (R_H) (β_s°) of *Acacia senegal* gum (*Asen*), IEC-F1 and IEC-F2 obtained from dynamic light scattering (DLS). Measurements were done in 5 g.L^{-1} prepared in deionized water.

	<i>Asen</i>	Fraction IEC-F1	Fraction IEC-F2
R_H^a (nm)	50	70	35
Populations (nm)	6; 28; 150	17; 75; 250	6; 18; 49

^a R_H was calculated from the autocorrelation curve (Fig. 5), assuming a Gaussian distribution of the molecules. Molecule populations were calculated using the NICOMP method.

hydrodynamic radius (z-average) are presented in Table 5. The results show a clear influence of the presence of supramolecular assemblies in the IEC-F1 fraction, since for the same decay time a higher intensity of the signal was measured. As expected, the high aggregate-content IEC-F1 fraction displayed a higher R_H (70 nm) than *Asen* and IEC-F2 (50 and 35 nm, respectively). Furthermore, IEC-F1 showed three molecule populations with a R_H around 17, 75 and 250 nm. Thus, the presence of large supramolecular assemblies in this fraction was confirmed. Presence of supramolecular assemblies of around 150 and 125 nm were also seen in experiments performed using HIC-F2 and HIC-F3, respectively (results not shown). Thus, further self-aggregation induced by the presence of HIC-F2 and HIC-F3 was suggested.

3.3.6. Volumetric properties of fractions IEC-F1 and IEC-F2

The volumetric properties (e.g. partial specific volume and partial specific adiabatic compressibility coefficient) can be related to solvent-solute interactions and have been used to predict the structure and flexibility of macromolecules (Gekko & Hasegawa, 1986; Gekko & Yamagami, 1991; Hoiland, 1986). The partial specific volume (v_s°) is defined as the change of the system volume due to the addition of an infinitesimal amount of the solute (Gekko & Hasegawa, 1986; Gekko & Yamagami, 1991; Hoiland, 1986; Mejia Tamayo et al., 2018) and can be determined from the following relationship:

$$v_s^\circ = \frac{1}{\rho_0} \lim_{c \rightarrow 0} \frac{\rho - \rho_0}{C} \quad (1)$$

where: ρ_0 and ρ are the density of the solvent and dispersion, C is the concentration of the solute.

The partial adiabatic compressibility coefficient (β_s°) is defined as the change of the system pressure caused by the addition of an infinitesimal amount of the solute. It can be determined from density and sound velocity of the dispersion using the following expression (Gekko & Hasegawa, 1986; Gekko & Yamagami, 1991; Hoiland, 1986; Mejia Tamayo et al., 2018):

$$\beta_s^\circ = \left(\frac{\beta_{so}}{v_s^\circ} \right) \lim_{c \rightarrow 0} \left[\frac{\beta/\beta_{so} - \Phi}{C} \right] \quad (2)$$

where: β and β_{so} are the adiabatic compressibilities of the dispersion and solvent and Φ is the apparent specific volume ($\Phi = (\rho - C)/\rho_0$). The adiabatic compressibility can be determined using the Newton Laplace equation: $\beta = \frac{1}{\rho u^2}$.

Both properties depend mainly on the intrinsic contribution of the solute and its hydration. The first one refers to the constitutive volume of the molecule itself: the atoms forming the molecule (van der Waals volume) and the cavities formed in the interior of the molecule due to imperfect packing and hydrophobicity of the molecule. The hydration contribution refers to the solute-solvent interactions due to changes in physicochemical properties of interacting water molecules. Changes in v_s° and β_s° are attributed to changes in the cavities or hydration. The first one has a positive effect on v_s° , suggesting a more flexible structure. Conversely, the second one has a negative effect on v_s° , suggesting a less flexible structure (Chalikian & Breslauer, 1996; Gekko & Noguchi, 1979).

Fig. 5. Autocorrelation curves of: *Acacia senegal* gum (*Asen*, egi10HHMDRSV0P), IEC-F1 (egi10F1PN563G0) and IEC-F2 (egi10M13FFB2KT) fractions. Measurements were performed at 5 g.L^{-1} in deionized water (pH 5) at 25°C using dynamic light scattering (DLS). $g^{(1)}$: the intensity of the signal (photon count, in vertical axis); τ : the decay time (s, in horizontal axis).

Table 6

Partial specific volume (v_s°) and partial specific adiabatic compressibility (β_s°) of *Acacia senegal* gum (Asen) and fractions HIC–F2, HIC–F3, IEC–F1, IEC–F2 and IEC–F1T.

	v_s° (cm ³ g ^{−1})	β_s° (x10 ¹¹ Pa ^{−1})
Asen ^a	0.5842	−12.2
HIC–F2 ^a	0.5876	−14.4
HIC–F3 ^a	0.6500	−1.0
IEC–F1	0.6095	−9.42
IEC–F2	0.5823	−12.9
IEC–F1T ^b	0.6313	−5.0

^a Values taken from Mejia Tamayo et al. (2018).

^b Calculated considering that IEC–F1 is composed by 70% of HIC–F3 and 30% of HIC–F2.

The volumetric properties, v_s° and β_s° , of the IEC–F1 and IEC–F2 fractions are presented in Table 6. IEC–F1 presented higher values of v_s° and β_s° (0.6095 cm³g^{−1} and -9.42×10^{-11} Pa^{−1}, respectively) than the IEC–F2 fraction (0.5823 cm³g^{−1} and -12.9×10^{-11} Pa^{−1}, respectively). Furthermore, using the reported values of the HIC–F1 and HIC–F2 fractions reported and assuming that IEC–F1 is composed of 70% HIC–F3 and 30% HIC–F2, the theoretical partial specific volume (v_{sT}°) and partial specific adiabatic compressibility (β_{sT}°) were calculated. Both, v_{sT}° and β_{sT}° are higher than the experimental ones (0.6313 cm³g^{−1} and -5×10^{-11} Pa^{−1}, respectively). The differences between the theoretical and experimental v_s° , can be explained due to the presence of supramolecular assemblies on IEC–F1 as it was evidenced using size exclusion chromatography (HPSEC–MALLS) and dynamic light scattering (DLS). Interestingly, both v_s° and β_s° are higher than the values previously reported for Asen by Mejia Tamayo et al. (2018) (0.584 cm³g^{−1} and -12.2×10^{-11} cm³g^{−1}, respectively). Since, the fraction IEC–F1 is mainly formed of the HIC–F2 and HIC–F3 fractions, which are less hydrated and more flexible molecules, the results are consistent with a more flexible and less hydrated structure. Furthermore, since protein interfacial properties have been clearly related to their molecule flexibility (Gekko & Yamagami, 1991) and based on their partial specific volume, v_s° , (0.588 and 0.650 cm³g^{−1}, respectively), these fractions have better interfacial properties. It is expected then that fraction IEC–F1 will have better interfacial properties compared to Asen, thus better foaming and emulsifying properties (Damodaran, 2008). All these results, and knowing that IEC–F1 exhibits a composition close to those from HIC–F2 and HIC–F3, are in coherence with the data previously reported by Mejia Tamayo et al. (2018). These authors found that HIC–F2 and HIC–F3 were the less polar AGP, according to its HIC elution order and protein content. Therefore, IEC–F1 will be able to bind less water molecules, and consequently will have a less hydrated and more flexible structure than HIC–F1.

4. Conclusions

We have achieved to obtain a fraction rich in aggregates from Asen gum through ion exchange chromatography using DEAE Sephacel gel as stationary phase. As expected, and according to Yariv detection, the two obtained fractions belong to AGP family, being called fraction IEC–F1 and fraction IEC–F2. We have thoroughly characterized the fraction IEC–F1, which presents similarities with both “classical” fractions HIC–F2 and HIC–F3. From the amino acid composition, we have estimated that fraction IEC–F1 corresponds theoretically to 70% of HIC–F3 and 30% of HIC–F2, and we have calculated the composition of a theoretical fraction named IEC–F1T. Significant differences between the molar mass distribution, the M_w and M_n values and the intrinsic viscosity of IEC–F1 fraction and those calculated for IEC–F1T were observed. We have also found high value for the R_g parameter of fraction IEC–F1. Similarly, the results of Mark–Houwink–Sakurada

(MHS) analysis for fraction IEC–F1 show a low hydrodynamic coefficient value. All these experimental data obtained in IEC–F1 fraction, as well as its observed differences with the theoretical IEC–F1T calculated fraction were clearly attributed to the gain of aggregates. Moreover, from the hydrodynamic radius, further self-aggregation induced by the presence of HIC–F2 and HIC–F3 can also be deduced. Finally, the theoretical partial specific volume and partial specific adiabatic compressibility of fraction IEC–F1T were different from the experimental ones, which can be likewise explained due to the presence of supramolecular assemblies on IEC–F1. Summarizing, our results indicate a great tendency of fraction IEC–F1 to aggregate. The enrichment of naturally occurring aggregates together with the additional aggregation phenomena supported by the particular IEC conditions caused the mentioned gain of aggregates.

Conflict of interest

The authors declare that they have no conflict of interest.

Compliance with ethics requirements

This article does not contain any studies with human or animal subjects.
