Abstract

In many applications, separable algorithms have demonstrated their efficiency to perform high performance volumetric processing of shape, such as distance transformation or medial axis extraction. In the literature, several authors have discussed about conditions on the metric to be considered in a separable approach. In this article, we present generic separable algorithms to efficiently compute Voronoi maps and distance transformations for a large class of metrics. Focusing on path-based norms (chamfer masks, neighborhood sequences), we propose efficient algorithms to compute such volumetric transformation in dimension \( n \). We describe a new \( O(n \cdot N^n \cdot \log N \cdot (n + \log f)) \) algorithm for shapes in a \( N^n \) domain for chamfer norms with a rational ball of \( f \) facets (compared to \( O(f^{\frac{n}{2}} \cdot N^n) \) with previous approaches).

Last we further investigate a more elaborate algorithm with the same worst-case complexity, but reaching a complexity of \( O(n \cdot N^n \cdot \log f \cdot (n + \log f)) \) experimentally, under assumption of regularity distribution of the mask vectors.

1. Introduction

Volumetric analysis of digital shapes is crucial in many geometry processing applications, for instance to measure distances between two points in \( \mathbb{Z}^n \), or to measure the width of a shape or the proximity between two shapes. Since early works on digital geometry, distance transformation has been widely investigated (\textit{e.g.} Rosenfeld and Pfaltz (1968)). Given a finite input shape \( X \subset \mathbb{Z}^n \), the distance transformation labels each point in \( X \) with the distance to its closest point in \( \mathbb{Z}^n \setminus X \). Labeling each point by the closest background point leads to Voronoi maps (\textit{e.g.} the restriction to \( \mathbb{Z}^n \) of Voronoi diagrams from computational geometry (de Berg et al., 2000)). Distance transformation (or distance field) is a key tool in many applications such as shape modeling, shape matching, geometry processing, motion planing, object tracking… (see Fabbri et al. (2008) or Jones et al. (2006) for surveys of techniques and applications).

In this article, we propose a theoretical analysis to speed up the distance transformation computation for a large class of metric, allowing efficient and parallel implementations.

As the distance transform is parametrized by a distance function, many authors have addressed this distance transformation problem with trade-offs between algorithmic performances and the accuracy of the digital distance function with respect to the Euclidean one. Hence, authors have considered: distances based on chamfer masks (Rosenfeld and Pfaltz, 1968; Borgefors, 1986; Fouard and Malandain, 2005) or sequences of chamfer masks (Rosenfeld and Pfaltz, 1966; Mukherjee et al., 2000; Strand, 2008; Normand et al., 2013a); vector displacement based Euclidean distance (Danielsson, 1980; Ragnemalm, 1993); Voronoi diagram based Euclidean distance (Breu et al., 1995; Maurer et al., 2003) or square of the Euclidean distance (Hirata, 1996; Meijster et al., 2000). For the Euclidean metric, separable volumetric computations have demonstrated to be very efficient with the design of optimal \( O(n \cdot N^n) \) time algorithms for shapes in \([1,N]^n\) domains, optimal multithread/GPU implementation or extensions to toric domains (please refer to Coeur-
contributions (e.g. chamfer mask or weighted–neighborhood sequences) approximate the Euclidean distance as the length of shortest paths defined from sequences of displacement vectors on the grid (from a finite set of possible moves). Aside distance information, path-based approaches provide an explicit notion of discrete path that is not accessible for the Euclidean norm. Furthermore, the discrete and combinatorial nature of the distance function has been used to define efficient algorithms to extract discrete medial axis (Borgefors and Nyström, 1997; Remy and Thiel, 2002; Saha et al., 2016) as local maxima of the distance map. Normand et al. (2013b, 2014) further exploits the combinatorial structure of path-based distances to compute distance transformation in on-the-fly streaming context. In terms of distance transform computation, two main techniques exist. The first one considers a weighted graph formulation of the problem and Dijkstra-like algorithms on weighted graphs to compute distances. If \( m \) denotes the size of the chamfer mask, computational cost could be in \( O(m \cdot N^m) \) using a cyclic bucket data structure as suggested by Verwer et al. (1989). Another approach consists in a raster scan of the domain: first the chamfer mask is decomposed into disjoint sub-masks; then the domain grid points are scanned in a given order (consistent with the sub-mask construction) and a local computation is performed before being propagated (Rosenfeld and Pfaltz, 1966; Borgefors, 1986). Scanning the domain several times (one per sub-mask) leads to the distance transformation values. Again, we end up with a \( O(m \cdot N^m) \) computational cost. Besides specific applications which use the anisotropic nature of the chamfer mask, rotational dependency is usually enforced by increasing the mask size \( m \) (its number of vectors, see below) leading to expensive computational costs.

Contributions The goal of this work is to demonstrate that the linear factor in the mask size can be lowered down to a logarithmic one in any dimension for path-based metrics. This is achieved by first detailing and analyzing the separable distance transformation algorithm and briefly recalling the preliminary analysis of Coeurjolly (2014) for the 2D case, before extending it to higher dimensional distance transformation problems. More precisely, we describe efficient and parallel algorithms in arbitrary dimension \( n \) to compute error-free distance transformation and Voronoi map for chamfer norms and other path-based metrics. Overall computational costs are summarized in Table 1 (see 3.1 for the predicate definitions).

The article is organized as follows: First, we recall basic definitions and properties of path-based norms (Section 2). In Section 3 we clarify the separable \( n \)-dimensional Voronoi map extraction. Section 4 is a short discussion about the complexity of this algorithm for \( L_p \) metrics. Then Section 5 is dedicated to the design of a fast implementation of the separable algorithm for path-based metrics. In Section 6, we present and analyse the proposed \( n \)-dimensional algorithm for path-based metrics.

\[ \text{Many authors have proposed algorithmic and/or analytic approaches to construct chamfer norms approximating the Euclidean metric. Following Thiel (2001) and Fouard and Malandain (2005), we briefly recall here the} \]
classical construction of chamfer norms from Farey set since it will be the base of the study proposed in Section 6.

The Farey sequence \( \mathcal{F}_m^n \) of dimension \( n \) and order \( m \) is defined as follows: \( \mathcal{F}_m^n = \{ \left( \frac{x}{y}, \ldots, \frac{y}{m} \right) \} \), where \( \gcd_{i=1,n}(x_i) = 1 \). \( 0 \leq x_n \leq x_{n-1} \leq \cdots \leq x_1 \leq m \). Then a Farey sequence \( \mathcal{F}_m^n \) is in bijection with all the points \( (x_1, \ldots, x_n) \) in \( \mathbb{Z}^n \), \( 0 \leq x_n \leq \cdots \leq x_1 \leq m \) visible from the origin\(^1\). The vectors \( \vec{v}_k \) of a chamfer norm in dimension \( n \) can be defined using a subset of a particular \( \mathcal{F}_m^n \); the weights \( w_k \) are set so that the rational ball \( B_R \) (see Definition 3 below) is convex. By construction, such chamfer masks have axis symmetric unit balls and thus define chamfer norms.

2.3. Distance computation for chamfer norms

To evaluate distances between two digital points for a given chamfer norm, direct formulations have been proposed with a simple geometrical interpretation (Thiel, 2001; Normand and Évenou, 2009), using the so-called rational ball.

**Definition 3 (Rational ball, minimal H-representation)**

Given a Chamfer norm \( \mathcal{M} \), the rational ball associated with \( \mathcal{M} \) is the polytope

\[
B_R = \text{conv} \left\{ \vec{v}_k : (\vec{v}_k, w_k) \in \mathcal{M} \right\}.
\]

where \( \text{conv} \) denotes the convex hull of a set of points.

Rational balls for some 2D and 3D chamfer norms are illustrated in Figure 1. As any convex polytope, the rational ball \( B_R \) can also be described as the intersection of \( f \) linear constraints in dimension \( n \), \( f \) being the number of \( (n-1)-\) facets of \( B_R \). This is the H-representation of the polytope which can be written in a matrix form:

\[
B_R = \left\{ x \in \mathbb{R}^n : x = \sum_{k=1}^{m} \alpha_k \left( \frac{\vec{v}_k}{w_k} \right), \alpha_k \geq 0, \sum_{k=1}^{m} \alpha_k = 1 \right\} = \left\{ x \in \mathbb{R}^n : Ax \leq y \right\},
\]

where \( A \) is a \( f \times n \) matrix and \( y \) a vector of \( n \) values, so-called the H-coefficients (Ziegler, 2012). The H-representation of a polytope \( P \) is with minimal parameter if \( P = \left\{ x \in \mathbb{Z}^n : Ax \leq y \right\} \) with \( A \) being such that \( \forall k \in [1 \ldots f] \), \( \exists x \in P \) \( A_kx = y_k \) (Normand and Évenou, 2009).\(^2\) In other words, \( A \) is the minimal H-representation of \( B_R \) if each linear hyperplane of the H-representation of \( B_R \) contains at least one point in \( B_R \cap \mathbb{Z}^n \).

From Normand and Évenou (2009), an important result for distance computation can be summarized as follows:

**Proposition 1 (Direct Distance Computation)**

Given a chamfer norm \( \mathcal{M} \) and \( (A, y) \) its minimal parameter H-representation, then for any \( a \in \mathbb{Z}^n \), the chamfer distance of the point \( a \) from the origin is

\[
d_{\mathcal{M}}(O, a) = \max_{1 \leq k \leq f} \{ A_k a^T \}.
\]

Coming back to general path-based digital metrics, (weighted) neighborhood sequences have been proposed to have a better approximation of the Euclidean metric (Rosenfeld and Pfaltz, 1966; Mukherjee et al., 2000; Strand, 2008; Normand et al., 2013a). The main idea is to combine sequences of elementary chamfer norms. A key result has been demonstrated by Normand et al. (2013a) stating that for such distance functions, a minimal parameter polytope representation exists and that distances can be obtained from an expression similar to (3):

\[
d(O, a) = \max_{1 \leq k \leq f} \{ \gamma_k \{ A_k a^T \} \},
\]

\( \gamma_k : \mathbb{N} \rightarrow \mathbb{N} \) being some integer sequence characterizing the neighborhood sequence metric. As we will see in the next sections, direct distance computation is key to design an efficient distance transformation algorithm. Similarity of Equations 3 and 4 makes the algorithms presented in the following sections for chamfer norms easily generalizable to neighborhood sequences.

To conclude this preliminary section, algorithms efficiency is characterized by their asymptotic behavior using the \( O(\cdot) \) and \( \Theta(\cdot) \) notations\(^3\) as a function of the dimension, the number of vectors defining the chamfer norm and the domain size.

\(^1\) A point \( p \in \mathbb{Z}^n \) is visible from the origin in \( \mathbb{Z}^n \) if there is no point of \( \mathbb{Z}^n \) on \( (Op) \) between \( O \) and \( p \).

\(^2\) \( A_k \) being the \( k \)th row of \( A \).

\(^3\) In a computational model where arithmetic operations and scalar comparisons are constant time with: \( f(x) = O(g(x)) \leftrightarrow \exists C, x_0 \in \mathbb{R}^+, \forall x > x_0, |f(x)| \leq C \cdot g(x) \), and \( f(x) = \Theta(g(x)) \leftrightarrow \exists C, C', x_0 \in \mathbb{R}^+, \forall x > x_0, C \cdot g(x) \leq |f(x)| \leq C' \cdot g(x) \).
3. Separable distance transformation

3.1. Voronoi map from separable approach and metric conditions

Several authors have described optimal in time and separable techniques to compute error-free Voronoi maps or distance transformations for $L_2$ and $L_\infty$ metrics (Breu et al., 1995; Hirata, 1996; Meijster et al., 2000; Maurer et al., 1995). Separability means that computations are performed dimension by dimension. In the following, we consider the Voronoi Map approach as defined by Breu et al. (1995). Given a digital set $X$ defined on an hyper-rectangular domain $[1..N_1] \times \ldots \times [1..N_n]$, let us first define the image $I_X : [1..N_1] \times \ldots \times [1..N_n] \rightarrow \{0, 1\}$ such that $I_X(a) = 1$ for $a \in [1..N_1] \times \ldots \times [1..N_n]$ iff $a \in X$ ($I_X(a) = 0$ otherwise). The separable algorithm that computes the Voronoi Map for $I_X$ is defined in Algorithm 1 and works on the image spans for each dimension. An image span $S$ along dimension $q$ is a vector of $N_q$ points with same coordinates except at their $q^{th}$ one. The $q^{th}$ coordinate of a point $a \in \mathbb{Z}^n$ is denoted by $a_q$. A given span $S$ in dimension $q$ is denoted by $\{s^{(q)}\}_{i=1..N_q}$. In Algorithm 1 the Voronoi map is first initialized by processing each span of the input image along the first dimension in order to create independent 1D Voronoi maps for the metric (lines 5 – 6). Then, for each further dimension $q$, the partial Voronoi map $\Pi_X$ is updated using one dimensional independent processes on each span along the $q^{th}$ dimension (line 8).

Algorithm 2 describes the function $\text{VORONOI\_MAP}(\text{SPANN}(I_X, q, S))$. This function is the core of the separable algorithm as it defines the 1D processes to perform on each row, column and higher dimensional image span. In this process, metric information are embedded in the following key predicates (see Fig. 2):

1. $\text{CLOSEST}(a, b, c)$: given three points $a, b, c \in \mathbb{Z}^n$ this predicate returns true if $d(a, b) < d(a, c)$;
2. $\text{HIDDENBY}(a, b, c, S)$: given a 1D image span $S$ parallel to the $q^{th}$ coordinate axis, and three points $a, b, c \in \mathbb{Z}^n$ such that $a_q < b_q < c_q$, this predicate returns true if there is no $s \in S$ such that $d(b, s) < d(a, s)$ and $d(b, s) < d(c, s)$. (5)

\[
\text{Algorithm 1: } \text{VORONOI\_MAP}(\text{BINARY\_MAP}(I_X))
\]

$\text{Pi}_X = \text{empty image, same size as } I_X$;

for $q$ in $\{1..n\}$ do

for $(x_1, \ldots, x_{q-1}, x_{q+1}, \ldots, x_n)$ in $[1..N_1] \times \ldots \times [1..N_{q-1}] \times [1..N_{q+1}] \times \ldots \times [1..N_n]$ do

$S = \{s^{(q)}\}_{i=1..N_q}$ where $s^{(q)} = (x_1, \ldots, x_{q-1}, i, x_{q+1}, \ldots, x_n)$;

// all the coordinates are fixed in $S$ except the $q^{th}$ one

if $q = 1$ then

// $\Pi_X$ is initialized span by span

$\Pi_X = \Pi_X \cup \text{VORONOI\_MAP\_SPAN}(I_X, q, S)$;

else

// $\Pi_X$ is updated along span $S$

$\Pi_X = \text{VORONOI\_MAP\_SPAN}(\Pi_X, q, S)$;

return $\Pi_X$

In other words, $\text{HIDDENBY}$ returns true if and only if the Voronoi cells of sites $a$ and $c$ hide the Voronoi cell of $b$ along $S$. 

---

Figure 1: Chamfer masks and rational balls: in dimension 2, generator vectors for the mask $M_{3,4}$ (a), its rational ball (b). Generator vectors for $M_{3,7,11}$ (c) and its rational ball (d). In dimension 3, rational ball of a chamfer mask obtained using generator vectors $(x, y, z)$ $\in [-3,3]^3$ and weights computed following Fouard and Malandain (2005).
Algorithm 2: VoronoiMapSpan\(\text{Map} \mathcal{M}_X, \text{dimension } q, 1\text{D span } S\)

**Data:** \(q\) is an integer in \([1 \ldots n]\); 
\(S\) is a 1D span along dimension \(q\), with points \(\{s^1, \ldots, s^n\}\) sorted by their \(q^\text{th}\) coordinate; 
\(\mathcal{M}_X\) is either a binary map if \(q = 1\) or a partial Voronoi Map. 

**Result:** Partial Voronoi map \(\Pi_X\) updated along \(S\). 

1. if \(q == 1\): // Special case for the first dimension
   2. \(\Pi_X = \text{empty image, same size as } \mathcal{M}_X\); 
   3. \(k = 0;\)
   4. foreach point \(s\) in \(S\) do
      5. if \(M_X(s) == 0\) then // if \(s \in \mathbb{Z}^n\backslash X\)
         6. \(L_2[k] = s;\)
         7. // \(L_2\) = list of the sites visible on \(S\)
         8. \(k++;\)
   9. else
      10. \(\Pi_X = \mathcal{M}_X;\)
      11. \(L_2[0] = \mathcal{M}_X(s^1);\)
      12. \(L_2[1] = \mathcal{M}_X(s^2);\)
      13. \(k = 2; f = 3;\)
      14. // Update the list \(L_2\)
      15. while \(l \leq N_q\) do
         16. \(w = \mathcal{M}_X(s^l);\)
         17. while \(k \geq 2 \text{ and } \text{HiddenBy}(L_2[k - 1]; L_2[k], w; S)\) do
            18. \(k--;\)
            19. \(k++; l++;\)
            20. \(L_2[k] = w;\)
      21. foreach point \(s\) in \(S\) by increasing \(q^\text{th}\) coordinate do
         22. while \((k < |L_2|) \text{ and } \text{Closest}(s, L_2[k + 1]; L_2[k])\) do
            23. \(k++;\)
      24. return \(\Pi_X\)

**Remark.** Note that by construction, for a given span \(S\) along dimension \(q\), points \(a, b, c\) given as parameters to the \text{HiddenBy} predicate necessarily verify \(a_q \neq b_q \neq c_q\).

Indeed, these points are defined as the (partial) Voronoi map images of three points \(s^i, s^j, s^k (i \neq j \neq k)\) of \(S\), therefore having their \(q^\text{th}\) coordinate equal to \(i, j, k\) respectively (see lines 11, 12, 15 of Algorithm 2, and Figure 3 for an illustration).

For \(L_1, L_2\) and \(L_\infty\) metrics, \text{Closest} and \text{HiddenBy} predicates can be computed in \(O(n)\) in dimension \(n\) (Breu et al., 1995; Maurer et al., 2003). Hence, Algorithm 2 is in \(O(n \cdot N_q)\) for the dimension \(q\), leading to an overall computational time for the Voronoi Map (Algorithm 1) and Distance Transformation computations in \(\Theta(n^2 \cdot N^n)\) (if we assume that \(\forall q \in [1 \ldots n], N_q = N\)). Note that for \(L_p\) metrics, we can derive a \(\Theta(n \cdot N^n)\) algorithm as suggested in Hirata (1996); Meijster et al. (2000) using the following observation: when evaluating the \text{Closest} predicates in line 21 of Algorithm 2, we compare distances along the 1-D span of dimension \(q\). If we store the partial power \(p\) of the distance to the closest site \(a\) for each grid point \(y\) for previous dimensions (i.e. the sum \(\sum_{i=1}^{q-1} (a_i - y_i)^p\)), such distance comparisons can be obtained in \(O(1)\). Similar arguments can be used for the \text{HiddenBy} predicates of line 16, leading to the overall computational cost in \(\Theta(n \cdot N^n)\).

Figure 2: Geometrical predicates for Voronoi map construction Coeurjolly (2014): \text{HiddenBy}(a, b, c; S) returns true in (a) and false in (b) (straight segments correspond to Voronoi diagram edges). (c) illustrates the \text{Closest}(a, b, c) predicate for \(a \in S\).

![Figure 2](image-url)

Figure 3: For two points \(s^i\) and \(s^j\) (in purple) on a span \(S\) along dimension \(q\) (in red), the partial Voronoi map images \(M_X(s^i)\) and \(M_X(s^j)\) (in black) respectively have \(i\) and \(j\) as \(q^\text{th}\) coordinate.

Hirata (1996) or Maurer et al. (2003) discussed about conditions on the metric \(d\) to ensure that Algorithm 2 is correct. The key property can be informally described as follows: given two points \(a, b \in \mathbb{Z}^n\) such that \(a_q < b_q\) and a
straight line \( l \) along the \( q \)th direction and if we denote by \( v_l(a) \) (resp. \( v_l(b) \)) the intersection between the Voronoi cell of \( a \) (resp. \( b \)) and \( l \), then \( v_l(a) \) and \( v_l(b) \) are simply connected Euclidean segments and \( v_l(a) \) appears before \( v_l(b) \) on \( l \) (so called monotonicity property by Maurer et al. (2003) and is related to quadrangle inequality by Hirata 1996). These contributions are summed up in Definition 4 and Proposition 2.

**Definition 4 (Axis symmetric ball norm)** A metric \( d \) induced by a norm whose unit ball is symmetric with respect to grid axes is called axis symmetric ball norm.

**Proposition 2 (Metric conditions (Hirata, 1996))** Algorithm 1 exactly computes the Voronoi Map \( \Pi_X \) of a binary input image \( I_X \) for any axis symmetric ball norm.

Proposition 2 implies that most chamfer norms and neighborhood sequence based norms can also be considered in separable Algorithm 1 (see Fig. 4). However, note that Algorithm 2, and as a by-product Algorithm 1, are exact only if the distance comparison predicate is exact, i.e. if we can compare distances, through the \textsc{Closest} and \textsc{HiddenBy} predicates, without error.

Furthermore, computational efficiency of the algorithm requires the design of efficient algorithmic tools to implement these predicates, and this the purpose of the next sections.

3.2. Generic predicates and complexity analysis for axis symmetric ball norms

We first detail the overall computational cost of Algorithms 2 and 1. We assume in the following that \( \forall q \in [1 \ldots n], N_q = N \).

**Lemma 1 (Maurer et al. 2003; Coeurjolly 2014)** Let \((\mathbb{Z}^n, F, d)\) be a metric space induced by a norm with axis symmetric unit ball. If \( C \) denotes the computational cost of \textsc{Closest} predicate and \( H \) is the computational cost of the \textsc{HiddenBy} predicate, then Algorithm 2 is in \( O(N \cdot (C + H)) \), leading to a complexity of \( O(n \cdot N^n \cdot (C + H)) \) for Algorithm 1.

For a given axis symmetric ball norm \( d \), generic Algorithms 3, 4 and 5 were defined in Coeurjolly (2014). Note that these algorithms are valid for any dimension \( n \). The computational cost of the \textsc{Closest} predicate is simply the one of a distance evaluation. As a first approach, Algorithms 4 and 5 show that the \textsc{HiddenBy} predicate can be obtained by a binary search on the 1D image span \( \tilde{S} \) to localize the abscissa of Voronoi edges of sites \( \{a, b\} \) and \( \{b, c\} \).

**Algorithm 3:** Generic \textsc{Closest}(\( a, b, c \in \mathbb{Z}^n \)).

1. return \( d(a, b) < d(a, c) \);

The complexity \( H \) of Algorithm 5 can be expressed as a function of the complexity \( C \) of Algorithm 3, leading to the general result below:

**Lemma 2 (Coeurjolly 2014)** Let \( M \) be a chamfer norm with axis symmetric unit ball in dimension \( n \) whose rational ball has \( f \) facets, Algorithm 1 can be implemented with a computational complexity of \( O(n \cdot N^n \cdot C \cdot \log N) \), where \( N^n \) is the size of the image.

4. Distance transformation for \( L_p \) metrics

As a direct consequence of Lemma 1, we briefly derive computational costs for \( L_p \) metrics. For such metrics, as discussed in Section 3.1, the \textsc{Closest} and \textsc{HiddenBy}
5. Distance transformation in higher dimension for chamfer norms

In this section, we consider digital metrics given by chamfer norms and propose an efficient algorithm to compute the separable distance transformation for such metrics in nD. In Coeurjolly (2014), the structure of the rational ball of a chamfer mask in dimension 2 was used to obtain an $O(\log m)$ algorithm for the CLOSEST predicate, and an $O(\log^2 m)$ one for the HIDDENBY predicate, leading to an overall $O(\log^2 m \cdot N^2)$ algorithm for the separable distance transformation (see Table 1). The following sections extend these results to higher dimensions.

5.1. Definitions and general principle

Let us consider a general chamfer norm in arbitrary dimension $n$ with $m$ weighted chamfer vectors. As explained in Section 2, these vectors define a rational ball $B_R$ (see Definition 3), the center of which can be any point $p$. We define a wedge $(p,f_k)$ as the conical hull of $p$ (called the apex) and the vertices of a given facet $f_k$ of $B_R (k \in \{1..f\}$ if $B_R$ has $f$ facets). Thus, to each wedge is associated a row $A_k$ of the matrix of the minimal $H$-representation of $B_R$. Note that $A_k$ can also be seen as a non-unitary - normal vector to the facet $f_k$, as quoted by Normand and Evenou (2009). In the following, given a point $a$ and a point $p$, we denote by $(a, F^a(p))$ the wedge of apex $a$ containing point $p$, $F^a(p)$ being one face of $B_R$ (see Figure 5).

Using similar notations, Thiel (2001) and Strand (2008) demonstrated that distance evaluation between a point $a$ and a point $p$ can be obtained in two steps: first, compute the wedge $(a, F^a(p) = f_k)$; then

$$d_M(a, p) = A_k.(p-a)^T.$$  \hspace{1cm} (6)

Thus, implementing the CLOSEST predicate comes down to computing the wedge a given point belongs to. In 2D, it was shown in Coeurjolly (2014) that a binary search over the chamfer vectors was enough. The nD case is discussed in section 5.2.

Let us now see how to optimize the HIDDENBY predicate, which comes down to optimizing the VORONOIEDGE function. Given two points $a$ and $b$ ($a_q < b_q$) and a 1D image span $S$ along the $q^{th}$ dimension, we have to find the point $e$ of $S (e \in \mathbb{Z}^n)$ with abscissa $e_q$.
such that all the points of S of abscissa lower than \( e_q \) are in the Voronoi cell of \( a \) while all the points with a greater abscissa are in the Voronoi cell of \( b \). To compute \( e_q \) let us define \( l(S) \) as the one-dimensional flat that contains all the points of \( S \) and consider the Euclidean point \( \xi \in l(S) \) satisfying:

\[
d_M(a, \xi) = d_M(b, \xi).
\]

In other words, we are looking for the point in \( l(S) \) which is equidistant to \( a \) and \( b \). To compute \( \xi \), we first suppose that we know the two wedges \( (a, F^a(\xi) = f_k) \) and \( (b, F^b(\xi) = f_l) \) (see Fig. 6-(b)). In this situation, \( \xi \) is the solution of

\[
A_k \cdot (\xi - a)^T = A_l \cdot (\xi - b)^T.
\]

Note that since \( \xi \in l(S) \), we have one linear equation with only one unknown, \( \xi_q \). As a consequence, if we know the two wedges point \( \xi \) belongs to, we have its \( q \)-th coordinate \( \xi_q \) in \( O(1) \). As \( A \) is the minimal representation of \( B_R \), it has rational components and thus \( \xi \) has integer coordinates except \( \xi_q \) which is rational. Finally, the integer point \( e \in S \) is given such that \( e_q = |\xi_q| \).

The next section is dedicated to the CLOSEST predicate while in section 5.3 we detail how to efficiently compute the wedges \( (a, F^a(\xi) = f_k) \) and \( (b, F^b(\xi) = f_l) \), summarized in Algorithm 7 (see also Fig. 6-(b)).

5.2. CLOSEST predicate and first results

To begin with, let us discuss about the combinatorics of the chamfer norm rational ball. If \( m \) denotes the number of weighted vectors of \( M \), its rational ball \( B_R \) has \( O(m^{\frac{1}{2}+}) \) \( i \)-facets (for all \( 0 \leq i \leq n \) (de Berg et al., 2000). If \( f \) denotes the number of \( (n-1) \)-facets of \( B_R \), then we have:

**Lemma 3** Let \( M \) be a chamfer norm whose rational ball \( B_R \) has \( f \) \( (n-1) \)-facets in dimension \( n \), then distance computation and thus CLOSEST predicate are in (amortized) \( O(n + \log f) \) with \( O\left(\frac{f^{\frac{1}{2}+}}{(\log f)^{\frac{1}{2}+\delta}}\right) \) space and preprocessing time\(^4\).

\(^4\delta \) is an arbitrarily small positive constant.

The proof is given in Appendix A.

Algorithm 4 being valid in any dimension, we can merge this result with Lemma 2 to straightforwardly obtain the result below:

**Lemma 4** Let \( M \) be a chamfer norm whose rational ball \( B_R \) has \( f \) \( (n-1) \)-facets in dimension \( n \), separable exact Voronoi Map \( \Pi_X \) can be obtained in \( O(n \cdot N^n \cdot \log N \cdot (n + \log f)) \), thanks to a preprocessing in \( O\left(\frac{f^{\frac{1}{2}+}}{(\log f)^{\frac{1}{2}+\delta}}\right) \).

However, we show below that we can still expect faster \textsc{VoronoiEdge} function even in higher dimension.

5.3. Improved \textsc{HiddenBy} predicate

In dimension 2, it was shown in Coeurjolly (2014) that it was possible to reduce the complexity from a logarithmic factor on the size \( N \) of the image to a logarithmic factor on the size \( m \) of the mask using binary search over chamfer vectors. This process cannot be extended straightforwardly in higher dimensions since chamfer vectors cannot be ordered to perform a binary search anymore. However, it is interesting to notice that, whatever the dimension \( n \), vectors from a given point \( a \) to any point of a span \( S \) lie in the smallest affine subspace containing \( a \) and the one-dimensional flat \( l(S) \).
(see Fig. 5). The vertices of this polygon could be used to define a set of vectors on which a binary search could be performed as in the 2D case Coeurjolly (2014). However, since a 2-flat is actually the intersection of \( n-2 \) hyperplanes, computing this polygon comes down to intersecting a \( n \)-polytope with \( n-2 \) hyperplanes. By duality, each of these operations is equivalent to a convex hull computation, with a complexity of \( \mathcal{O}(f^{(n/2)}) \) (Chazelle, 1993; Bajaj and Pascucci, 1996). As a consequence, in order to make the approach efficient, we must avoid to compute explicitly this intersection.

This is achieved by rewriting the \textsc{VoronoiEdgeWedge} function as presented in Algorithm 6. As before, let \( e \in \mathbb{Z}^n \) be the point on \( S \) such that all the points of \( S \) of abscissa lower than \( e \) are in the Voronoi of \( a \) while all the points with a greater abscissa are in the Voronoi cell of \( b \). Given a, the goal of this function is to find the wedge of \( B_k \) (of apex \( e \)) \( e \) belongs to.

The algorithm computes two points \( s' \) and \( s' \) such that \( s' \) belongs to the Voronoi cell of \( a \) (if \( a_q < b_q, b \) otherwise), \( s' \) to the Voronoi cell of \( b \) (if \( a_q < b_q, a \) otherwise) and either \( j-i = 1 \) or \( F^a(s') = F^b(s') \). Similarly to generic Algorithm 4, this is done by performing a binary search over the points of \( S \), with a key difference on exit conditions: now, the algorithm does not wait until point \( e \) is found, but exits as soon as the two points \( s' \) and \( s' \) belong to the same wedge (line 1). Indeed, by convexity of the wedge, this implies that any point on \( S \) between \( s' \) and \( s' \) - and in particular \( e \) - also belongs to the same wedge. Correctness of the algorithm is ensured by maintaining two invariants: (i) \( s' \) is lower than \( s' \) on span \( S (s' < s' \); (ii) if \( a_q < b_q, s' \) is in \( a \)'s Voronoi cell, \( s' \) in \( b \)'s Voronoi cell, and conversely if \( b_q < a_q \).

Figure 6 illustrates the first step of the binary search in (a), and the situation at the end of the search in (b) (projection in plane \( p \)).

To remain now to use Algorithm 6 to compute point \( e \). Algorithm 7 implements the \textsc{VoronoiEdgeWedgeND} function as the \( nD \) counterpart of the \textsc{VoronoiEdgeWedge} function of Coeurjolly (2014). First, lines 1 to 11 are dedicated to checking whether the bisector of \( a \) and \( b \) crosses span \( S \) or not. If it does not, algorithm exits with an error code (lines 5 or 11). Otherwise, wedges \( (a, F^a(e)) (b, F^b(e)) \) are computed lines 12-13 calling the \textsc{VoronoiEdgeWedgeND} function (see Figure 6(b) for an illustration).

**Algorithm 6: VoronoiEdgeWedgeND**

\[
\text{if } f_i = f_j \text{ or } j-i = 1 \text{ then return } f_i; \\
\text{else mid } = i + (j-i)/2; \\
// Check whether \( s^{mid} \) is closest to \( a \) or to \( b \) \\
// \( O(n + \log f) \) evaluation of distances w.r.t. \( a \) and \( b \) \\
\text{Compute } f_i = F^a(s^{mid}); d(a, s^{mid}) = A_k \cdot (s^{mid} - a)^T; \\
\text{Compute } f_j = F^b(s^{mid}); d(b, s^{mid}) = A_k \cdot (s^{mid} - b)^T; \\
\text{if } d(a, s^{mid}) < d(b, s^{mid}) \text{ then } \\
\text{if } a_q < b_q \text{ then return } \textsc{VoronoiEdgeWedgeND}(a, b, mid, j, S, f_i, f_j) \\
\text{else return } \textsc{VoronoiEdgeWedgeND}(a, b, i, mid, S, f_i, f_j) \\
\text{else if } a_q < b_q \text{ then return } \textsc{VoronoiEdgeWedgeND}(a, b, i, mid, S, f_i, f_j) \\
\text{else return } \textsc{VoronoiEdgeWedgeND}(a, b, i, mid, S, f_i, f_j); \\
\]

**Proposition 3** Let \( M \) be a chamfer norm in dimension \( n \) whose rational ball \( B_k \) has \( f(n-1) \) facets. Let \( W \) be the computational time complexity of the \textsc{VoronoiEdgeWedge} function. Then, the separable exact Voronoi Map can be obtained in (amortized) \( O(n \cdot N^m \cdot (n + \log f + W)) \) with a \( O\left(\frac{f^{(n/2)}}{(\log f)^{n/2} \cdot f^{1/4}}\right) \) space and preprocessing time. More precisely, the worst-case complexity \( W \) being \( O((n + \log f) \cdot \log N) \), this leads to a global (amortized) complexity of \( O(n \cdot N^m \cdot \log N \cdot (n + \log f)) \) (same preprocessing).

The proof is given in Appendix B.

Note that in the worst-case, this approach does not improve the result presented in Lemma 4 (using the generic \textsc{VoronoiEdge} of Algorithm 4). However, in Section 6, we give some experimental insights on a finer analysis of the complexity \( W \) under distribution hypothesis.
Figure 6: View of the 2-flat \( P \): (a) Binary search initialization to compute the wedge \( (a, F^a(e)) \); (b) After completion of two binary searches, both wedges \( (a, f_k = F^a(e)) \) and \( (a, f_1 = F^b(e)) \) are known.

6. Experimental analysis

6.1. Insights on the complexity in dimension \( n \)

The complexity \( W \) of Algorithm 7 depends on the number of recursion steps done until points \( s^l \) and \( s^t \) are in the same wedge. Wedges being defined by the \( n-1 \) dimensional faces of \( B_R \), this complexity depends on the distribution of the chamfer vectors defining \( B_R \).

Let us denote by \( P \) the intersection between the \( (n-1) \)-faces of \( B_R \) and the 2-flat \( P \) (see the red polygon on Fig. 5). Note that \( P \) goes through the center of \( B_R \). If we assume that the vectors defining \( B_R \) are uniformly distributed on the unit sphere \( S^n \) and that the faces of \( P \) are also uniformly distributed on \( B_R \cap P \), then we can expect that \( W = O((n + \log f) \cdot \log |P|) \). Even if studying precisely these questions is out of scope of this work, in the following we give insights on both the relevance of these assumptions and the behaviour of \( |P| \) in the context of chamfer norms.

Algorithm 7: \textsc{VoronoiEdgeND}(\( a, b \in \mathbb{Z}^n \), span \( S \)).

```c
// Check that the bisector of \( a \) and \( b \) crosses span \( S \).
1 Compute \( f_{b_1} = F^b(s^1) \), \( f_{a_1} = F^a(s^1) \);
2 \( d(a, s^1) = A_{b_1} \cdot (s^1 - a)^T; \) \( d(b, s^1) = A_{a_1} \cdot (s^1 - b)^T; \)
3 if \( (a_q < b_q \text{ and } d(b, s^1) < d(a, s^1)) \) \{ or \( (b_q < a_q \text{ and } d(a, s^1) < d(b, s^1)) \}
4 then
5 Bisector does not cross \( S \). return -1.
6 else
7 Compute \( f_{b_q} = F^b(s^q) \), \( f_{a_q} = F^a(s^q) \);
8 \( d(a, s^q) = A_{b_q} \cdot (s^q - a)^T; \) \( d(b, s^q) = A_{a_q} \cdot (s^q - b)^T; \)
9 if \( (a_q < b_q \text{ and } d(a, s^q) < d(b, s^q)) \) \{ or \( (b_q < a_q \text{ and } d(b, s^q) < d(a, s^q)) \}
10 then
11 Bisector does not cross \( S \). return -1.

// Compute \( e \)
12 \( e = \text{VoronoiEdgeWedgeND}(a, b, 1, N, S, f_{b_1}, f_{b_k}); \)
13 \( f_l = \text{VoronoiEdgeWedgeND}(a, b, 1, N, S, f_{a_1}, f_{a_k}); \)
14 Compute abscissa \( \xi \) of the point \( \xi \in S \) such that
15 \( A_{a_1} \cdot (\xi - a)^T = A_{b_1} \cdot (\xi - b)^T; \)
16 return \( (\xi); \)
```

6.1.1. Some observations on the distribution hypothesis

To study the distribution of chamfer vectors, we consider chamfer masks where vectors are defined from a subset of Farey sequences, as presented in Section 2 (see also Thiel (2001) and Fouard and Malandain (2005)). Studying the distribution of such sets of vectors is a field of research in itself, and we simply mention below several results relevant to our context.

First, it is well-known from Markl (2013); Markl and Strömbergsson (2015) that \( n \)-dimensional lattice points visible from the origin have a constant density in \( \mathbb{R}^n \). Moreover, Boca et al. (2000) studied in the 2D case the distribution of the angles of straight lines from the origin through visible points. More precisely, they study the proportion of differences between consecutive angles which are larger than the average: they show that this proportion is smaller than what is expected for a random distribution, and give an explicit formulation of the repartition function. Similar results in higher dimension remain an open question.

These results tend to support the hypothesis of a uniform distribution of the vectors of \( B_R \), but the question of the distribution of the faces of the polygon \( P \) has not been investigated to our knowledge.
6.1.2. Experimental behaviour of \(|P|\)

In this part, we investigate the number of faces of \(P\) when \(B_R\) is a rational ball defined from Farey Sequences. The results are presented in Figure 7 and we detail below how the rational balls are generated, how the 2-flats \(P\) are selected, and how the intersection between \(B_R\) and \(P\) is performed.

In the four subfigures of Figure 7, rational balls are defined from Farey sequences:

- In (b-d), the vectors of \(B_R\) are all normalized vectors of a Farey sequence of order \(m\) (the higher the order, the greater the number of vertices - and \((n-1)\)-faces - of \(B_R\)). The order of the Farey sequences ranges from 1 to 10 in (b-c), from 1 to 6 in (d);

- in (a), \(B_R\) is computed thanks to the algorithm presented by Fouard and Malandain (2005).\(^5\) Given a (odd) mask size \(m\), and a maximal error \(\varepsilon\), the algorithm computes a subset of vectors of \(\mathcal{F}_{\frac{m-1}{2}}\) and weights such that the rational ball \(B_R\) is convex and the error with respect to the optimal theoretical error expected (wrt the Euclidean distance) for this mask size is below \(\varepsilon\).

Once the sets of vectors defined, we use Qhull (Barber et al., 1996) to compute both the rational ball itself and its intersection with a 2-flat \(P\) that goes through the center of \(B_R\). This intersection is performed by randomly picking the coefficients of \(n-2\) \((n-1)\)-hyperplanes containing the center of \(B_R\), and iteratively adding each \((n-1)\)-hyperplane. The vertices of \(P\) are the points lying on all \((n-1)\)-hyperplanes.\(^6\)

For each rational ball, a certain number of cuts is performed: from 1000 in dimension 3 to only 6 in dimension 5 for rational balls obtained from Farey sequences of order 5 and 6 (due to precision issues in Qhull). 95% confidence intervals are depicted for each point (\(i.e.\) for each rational ball) as error bars, but most of the time too small to be visible on the graphs. Note that this remark suggests that the size of \(|P|\) does not depend on the position of \(P\), thus supporting the uniform distribution hypothesis discussed in the previous section.

Analysing these results, we see that \(|P|\) seems to behave as \(f^\alpha\), with \(\alpha < 0\) and decreasing when the dimension increases. This suggests that, in practice, the complexity \(W\) of Algorithm 7 is expected to be \(O((n + \log f) \cdot \log f)\). Similarly to dimension 2 (Coeurjolly, 2014), this approach is expected to lower down the worst case complexity of the computation of the distance transformation for chamfer norms in dimension \(n\) from a logarithmic factor on the size \(N\) of the image, to a logarithmic factor on the size \(f\) of the rational ball.

6.2. Distance transformation in dimension 2

We evaluate the performance of the separable approach to compute restricted Voronoi diagrams and distance transformation for chamfer norms in dimension 2. First, we observe that using Algorithm 1 with the nD VORONOI EDGE (Alg. 7), we obtain an overall complexity in \(O(\log m \cdot \log N \cdot N^2)\) which is close to the \(O(\log^2 m \cdot N^2)\) complexity of the ad-hoc 2D version of the problem (Coeurjolly, 2014). These complexities have to be compared with the \(O(m \cdot N^2)\) complexity of the classical raster scan approach for chamfer norms (Borgefors, 1986). In Fig. 8-(a), we first illustrate some restricted Voronoi map results on small domains.

In Fig. 8-(b-c), we have considered a 2D domain 2048\(^2\) with 2048 random sites. First, we observe that fixing \(N\), the \(\log^2 \cdot m\) term is clearly visible in the computational cost of the Voronoi map (single thread curve). Bumps in the single thread curve may be due to memory cache issues. Please note that if we consider classical chamfer norm DT from raster scan (and sub-masks), the computational cost is in \(O(m \cdot N^2)\) and thus has a linear behavior (green curves in Fig. 8-(b-c)). Since we have a separable algorithm, we can trivially implement it in a multi-thread environment (here using OpenMP). Hence, on a bi-processor and quad-core (hyper-threading) Intel(R) Xeon(R) cpu (16 threads can run in parallel), we observe a speed-up by a factor 10 (orange curves in Fig. 8-(b-c)).

In Fig. 9, we present a shape processing experiment: when considering a chamfer norm mask with \(m = 100\), both the raster scan and our separable approaches produce the same distance transformation (Fig. 9-(c)) but the raster scan approach has been obtained in 520ms whereas our separable approach only requires

\(^5\)Code is available on the TC18 website [www.tc18.org/code_data_set/code.php](http://www.tc18.org/code_data_set/code.php)

\(^6\)Python code used to generate Farey sequences and to compute these graphs is available on [http://www.gipsa-lab.fr/~isabelle.sivignon/recherches_en.html](http://www.gipsa-lab.fr/~isabelle.sivignon/recherches_en.html)
25ms (note that since the domain is small $128 \times 127$, the OpenMP scheduler has only considered a single core for the separable Voronoi map computation).

Implementation of all separable algorithms are publicly available in the DGtal library (dgt).

7. Conclusion and Discussion

In this article, we have proposed generic algorithms to efficiently solve the restricted Voronoi map and distance transformation problems for a large class of metrics in any dimension. Focusing on chamfer norms, geometrical interpretation of this generic approach allows us to design an algorithm with logarithmic factors in the chamfer mask size compared to a linear one for previous approaches. Thanks to separability, parallel implementation of the distance transformation leads to efficient distance computation for path based metrics.

For the $L_2$ metric, (additively) weighted Voronoi maps, also known as power maps, can be used to solve the reverse distance transformation and medial axis extraction problem using similar separable techniques (Coeurjolly and Montanvert, 2007). A challenging future work would be to extend these results for path-based norms such as chamfer norms.

References

Appendix A. Proof of Lemma 3

Similarly to the 2D case, the distance $d_M(O,a)$ for $a \in \mathbb{Z}^n$ is given by first solving a ray-shooting problem on convex polytopes which consists in first computing the $(n-1)$-facet of $B_R$ pierced by the ray $(O,a)$ (see Fig. 5). Once the facet is obtained, the associated $A_k$ row is used to evaluate $d_M(O,a) = A_k \cdot a^T$ in $O(n)$. Following Matousek and Schwarzkopf (1993) Theorem 10, such a ray-shooting query on convex polytopes can be solved in $O(\log f)$ thanks to a preprocessing in $O\left(\frac{f^{\frac{2}{3}}}{(\log f)^{\frac{2}{3}} - 2}\right)$. In the case when the ray hits a facet of dimension strictly lower than $n-1$, the algorithm returns one of the adjacent $(n-1)$-facets. Propositions 3 and 4 from Normand and Évenou (2009) ensure that the choice of any $(n-1)$-facet leads to the same distance evaluation. Please note also that the preprocessing time is roughly equivalent to the convex hull computation in higher dimension which is in $O(f^{\frac{2}{3}})$. Hence, preprocessing for ray-shooting can be done while computing the rational ball $B_R$ using Eq. (2). □

Appendix B. Proof of Proposition 3

Following Lemma 1, the generic separable algorithms computes the Voronoi map in $O(n \cdot N^m \cdot (C + H))$. Lemma 3 states that $C = O(n + \log f)$ with a $O\left(\frac{f^{\frac{2}{3}}}{(\log f)^{\frac{2}{3}} - 2}\right)$ space and preprocessing time. Remains to evaluate $H$, i.e. the complexity of the VoronoiEdgeWedgeND function. In Algorithm 7, the first eleven lines are in $O(C)$ since only distance computations are involved. Lines 12 and 13 are calls to the VoronoiEdgeWedgeND function, with a complexity in $O(W)$. In the worst case, we have $W = O((n + \log f) \cdot \log N)$ thanks to the test $j - i = 1$ on line 1 of Algorithm 6. Last, the system to solve in line 14 has only one unknown $\xi_q$ since $\xi$ belongs to the one-dimensional span $S$, with a complexity of $O(1)$. □
Figure 7: Number of faces of $P$ with respect to the number of $(n - 1)$-faces of $B_R$ in different settings. In (a), $B_R$ is a rational ball as computed by Fouard and Malandain (2005) in dimension 3. In (b-c), $B_R$ is defined from a Farey sequence of given order and dimension, taking all the fractions: (b) dimension 3, for orders between 1 and 10, (c) dimension 4 for order between 1 and 10, (d) dimension 5 for orders between 1 and 6. Each point is the mean of a certain number of random cuts (1000 in dimension 3, 500 in dimension 4, 400 in dimension 5 for orders up to 4, and 6 in dimension 5 for orders 5 and 6.).
Figure 8: (a) Voronoi map (first and third columns) and distance transformation (second and fourth columns) for the chamfer norm of mask $M_{5-7-11}$, and the $L_p$ metrics $L_2$ and $L_{80}$.

The digital shape $X$ considered is the whole $[0, 256]^2$ domain except two random points in the first two columns, and 10 random points in the last two ones. (b) Experimental evaluation of the subquadratic algorithm when increasing the mask size on a $[0, 2048]^2$ image and following the chamfer norm construction of Fouard and Malandain (2005) (zoom in (c)). We compare the efficiency of Algorithm 1 in single thread and multi-thread settings, with the classical raster scan approach of Borgefors (1986) (only single thread).
Figure 9: Example of distance transformation based shape processing: (a) initial shape (128 × 127 domain), (b) its Voronoi map using a chamfer norm mask with 100 vectors, (c) its associated distance map.
