Nanophotonic circuits using group III-nitrides on silicon are still lacking one key component: efficient electrical injection. In this paper we demonstrate an electrical injection scheme using a metal microbridge contact in thin III-nitride on silicon mushroom-type microrings that is compatible with integrated nanophotonic circuits with the goal of achieving electrically injected lasing. Using a central buried n-contact to bypass the insulating buffer layers, we are able to underetch the microring, which is essential for maintaining vertical confinement in a thin disk. We demonstrate direct current room-temperature electroluminescence with 440 mW/cm² output power density at 20 mA from such microrings with diameters of 30 to 50 μm. The first steps towards achieving an integrated photonic circuit are demonstrated.

I. INTRODUCTION

The group III-nitride material system can emit light from the deep ultraviolet (UV) to visible (VIS) spectral range1, opening an extraordinary realm of possible applications for active photonic devices. Passive devices from the UV to the infra-red (IR) are conceivable thanks to the very large transparency window of III-nitrides. Opto-electronics based on III-nitrides, including blue/violet light emitting diodes (LEDs) and laser diodes (LDs) and white light LEDs are already being mass produced for consumer applications, such as general lighting and multi-color displays2. Potential applications for III-nitride nanophotonics, that is photonics utilizing microcavities, waveguides, and other devices interacting with light on the sub-wavelength scale, range from quantum technologies, such as single photon sources3, ion trapping4, and parametric down conversion5 to biosensing, III-nitrides being bio-compatible6,7. Over the past 15 years, there have been numerous demonstrations of III-nitride nanophotonic devices, including high quality factor optical microcavities8-11, microlasers12-22, and both passive23-28 and active29-31 photonic circuits on sapphire, silicon carbide, or silicon substrates.

Electrical injection was utilized only in very few cases in III-nitride microdisk cavities or photonic circuits12,22,29,30, yet a main interest in using III-nitrides is to have active emitters, which are much more feasible for applications if electrically driven as opposed to optically pumped. Efficient electrical injection continues to pose a challenge in thin III-nitride layers. However, the advantage of using silicon as a substrate for III-nitride nanophotonics is the possibility of monolithic integration into a well-established photonic platform, extending it to encompass UV-VIS emitters. Major difficulties in achieving low threshold and long lifetime electrically injected lasing are to sufficiently reduce the threading dislocation density (TDD) (usually in the order of 10⁹ – 10¹⁰ cm⁻²) in gallium nitride (GaN) grown on silicon which is caused by the large lattice mismatch of 17% and to reduce cracking due to the large difference in thermal expansion coefficient of 116% between GaN and silicon32,33. A significant dislocation density does not prevent to observe lasing as shown by Sun et al.32 who in 2016 demonstrated the first ever laser diode in the III-nitride on silicon material system with a TDD of 6 · 10⁸ cm⁻². Lasing has also been achieved with higher TDDs34. A standard GaN on silicon epilayer can thus be an appropriate test platform for nanophotonic circuits incorporating active laser devices, even if it has limitations for reliability under continuous wave electrical injection.

The field of III-nitride on silicon nanophotonics will greatly benefit from an electrical injection scheme compatible with thin epilayers. There have been some attempts at electrical injection in III-nitride photonic circuits for light communication29,30, however these have been on impractically large devices. Feng et al.22 recently demonstrated lasing under electrical injection in III-nitride "sandwich"-type microdisks on silicon, however, they are using 5.8 μm thick heterostructures and side contacts that do not allow for fabrication of high quality, efficient nanophotonic circuits. The need for side contacts can be avoided by via etching, which was demonstrated by Hikita et al. for field effect transistors using a lateral device structure35,36. A backside substrate and buffer layer removal approach for all vertical power diodes was proposed by Zhang et al.37.

III. EXPERIMENT AND DISCUSSION

The investigated sample was grown on a 2 inch n-type (doping concentration 5·10^{18} cm^{-3}) silicon (111) wafer using metal organic chemical vapor deposition (MOCVD). The heterostructure is illustrated in Fig. 3 (a). First an undoped buffer layer of 220 nm aluminum nitride (AlN) and 200 nm GaN was grown, followed by the LED heterostructure consisting of 400 nm GaN:Si (doping level 5·10^{18} cm^{-3}), 11.5 nm of undoped GaN, 5 pairs of 2.3 nm In_{0.14}Ga_{0.86}N quantum wells (QWs) and 11.5 nm GaN barriers, a 20 nm Mg-doped Al_{0.15}Ga_{0.85}N electron blocking layer (EBL) (doping concentration 4·10^{19} cm^{-3}), 90 nm of GaN:Mg (doping concentration 4·10^{19} cm^{-3}), and 15 nm of GaN:Mg (doping concentration 1·10^{20} cm^{-3}). The TDD estimated from X-ray diffraction (XRD) and atomic force microscopy (AFM) is in the range of 5·10^9 to 2·10^{10} cm^{-2} and the root mean square (rms) roughness is 1 nm as determined by an atomic force microscopy (AFM) scan of 10 μm × 10 μm. The device scheme proposed in this paper allows for much simpler heterostructures than required for the devices reported on by Feng et al., as no cladding layers are used.

Simulation of the vertical mode confinement of the TE_0, TE_1, and TE_2 modes are shown in Fig. 3 (b) for an underetched disk. The overlap of these modes with the QWs (without barriers) are 96.9%, 2.4%, and 2.0%, respectively. By increasing the thickness of the p-GaN cap layer, for example, we could increase this overlap of

FIG. 2. a) False color SEM images of a 50 µm diameter microring for electrical injection. b) Same device but from a different angle to emphasize the underetching of the microring. The metal microbridge and p-contact are highlighted in yellow, the insulator in red, and the III-nitride in purple. The rough gray area is the etched silicon.

FIG. 3. The sample structure: a) Detailed heterostructure, b) Simulated mode confinement of the TE₀, TE₁, and TE₂ modes, the MQW region is highlighted in green, the heterostructure in gray, c) Energy band structure of the sample at 3.4 V bias. The TE₀ mode to a maximum of 1.6 % for a 400 nm cap thickness. Laterally the mode is confined by total internal reflection at the edge of the disk, extending over a few microns. A simulation of the band structure is shown in Fig. 3 (c) under a 3.4 V bias, which corresponds to the GaN bandgap. Simulations of the radiative recombination show that the carrier density is higher in the QWs closer to the p-side and thus fewer wells may lead to an enhanced performance.

A typical current density over voltage (JV) curve of a 40 µm diameter microring is shown in Fig. 4 and is compared to the JV curve of a lateral LED with a 180 µm diameter p-contact and top n-contact on the n-GaN. The turn-on voltage is similar in both cases, which shows that the microring process with its multiple etch steps and small device dimensions, as well as taking the n-contact through the silicon substrate, do not have any negative influence on the device performance. The surface area of both p-contacts is very different, and a direct comparison of the current densities at a given voltage is not straightforward. For microrings the current density quickly becomes elevated. The overall high voltage in forward direction is due to the resistive p-GaN. The microring also shows a slightly leaky behavior in reverse bias. It is important to note that for the as-grown sample and when fabricating large mesas of 1 mm diameter, vertical conductivity through the buffer layers is observed even if the buffer is expected to be insulating, while mesas of around 200 µm diameter are vertically insulating. This indicates that the vertical conductivity is not...
simply driven by the dislocation density. We attribute this phenomenon to current flowing through macroscopic defects in the buffer layer and at the AlN/Si interface that might result from dislocation formation, dislocation bundles, inter-diffusion, and possibly cracks in large mesas. It also shows that the approach with the central annular contact is mandatory for micrometer-size devices. Meanwhile the central annular contact connected to the silicon substrate allows current injection through the substrate, which is an important technical option for III-nitride on silicon devices.

We performed direct current room-temperature electroluminescence (EL) measurements on these devices, using probe tips placed on the large p-pad and near the sample on the copper block for the n-contact through the silicon substrate. The emission is collected from the side of the sample with a microscope objective and the light is guided through air into a grating monochromator with a liquid nitrogen cooled charge-coupled device (CCD) as detector. Figure 5 (a) shows a photo of a 40 µm microring emitting blue EL. A cross-sectional view of the device along the red dashed line is shown at the top of the figure. The microring is at the center of a black 3/4 circle, which is etched to the Si substrate by ICP and isotropically etched by the XeF2 gas. On the right side of this circle is a 140 x 140 µm2 p-pad that connects to the microring via a microbridge. Figure 5 (b) shows spectra of a 40 µm diameter ring for currents from 3 to 15 mA measured using a 600 grooves/mm grating, an 80 µm slit width, and 0.01 s integration time. A slight blue shift is observed with increasing current. The maximum current of 15 mA corresponds to a current density of 4.2 kA/cm2, which is not sufficient to achieve lasing. Device degradation and breakdown are observed at currents between 15 and 30 mA, likely due to the not optimized insulator between the p- and n-contacts at the center of the microdisk. By using silicon nitride (SiN) instead of SiO2 better device performance should be attained. Feng et al. reported a lasing threshold of 25 kA/cm2 for devices with 40 µm diameter, while Kneissl et al. observed lasing at 7.8 kA/cm2 for 500 µm diameter devices on sapphire12,22. Under optical pumping we have observed rather high thresholds of around 3 mJ/cm2 per pulse for 5 µm diameter disks20 fabricated on similar material. No whispering gallery modes (WGMs) are observed using a 3600 grooves/mm grating with a spectral resolution of 0.02 nm. The free spectral range (FSR) of first-order modes in such a 40 µm diameter ring is expected to be around 0.4 nm, as extrapolated from finite-difference time-domain (FDTD) simulations for smaller devices. However, there are many competing families of modes, and it is not evident that the large spectral density of modes allows for an observation of WGMs below threshold. Both Kneissl et al. and Feng et al., who used devices in a similar diameter range do not observe any modes below threshold12,22. Hole diffusion is an issue in such devices due to the distance from the p-ring to the edge of the microdisk and tunnel junctions will be investigated as a potential solution. Figure 5 (c) shows a double logarithmic plot of the integrated intensity over current, depicting a slope of around 1 at high current injection, suggesting dominant radiative recombination, while non-radiative processes dominate at low current. This implies a good material quality, which could be further improved by combining a 3D growth mode during the buffer layer growth to reduce the TDD with growth on mesa patterned templates to reduce the tensile stress in the GaN layers to prevent their cracking39,40. We performed polarization measurements (not shown) at 0, 45, and 90°, indicating that the microring emission is mainly of transverse electric (TE) polarization, as expected for InGaN/GaN QWs41. Using an integrating sphere we determined the output power of a 40 µm diameter microring corresponding to the IV response in Fig. 4 to be 2 µW at 20 mA, giving an output power density of 440 mW/cm2 at a current density of 5.7 kA/cm2. This power density is below the one reported for microLEDs grown on sapphire42, but in the latter case a full optimization of collection efficiency is performed. Here the microring radiates preferentially in the layer plane, which is detrimental for collection efficiency, but an asset for in-plane coupling and nanophotonic circuits, as described below.

IV. PERSPECTIVES

In order to achieve lasing in such microring structures next steps will include a) replacing the SiO2 insulating layer with SiN to delay electrical breakdown, b) improving the lateral current spreading through the use of tunnel junctions, c) improving the vertical confinement and mode overlap by replacing the n-GaN layer with n-AlGaN, and d) lowering the dislocation density through selective area growth.

Furthermore, we envision to demonstrate a photonic circuit consisting of an electrically injected microring, a side-coupled bus waveguide with a small gap in the order of 100 nm, and grating out-couplers terminating the waveguide, as illustrated in Fig. 6, and as previously demonstrated under optical pumping31. This process is very challenging, as alignment precision between 20 nm for the e-beam lithography steps and 1 µm for the optical lithography steps are required, and proximity effect correction is needed when defining the microring and bus waveguide. Note that the etching of small gaps and narrow waveguides, which is essential for efficient evanescent coupling in the blue, requires the total heterostructure thickness to be less than 2 µm. Such devices will allow to demonstrate the viability of the III-nitride on silicon nanophotonic platform for real-world applications.

V. CONCLUSION

In conclusion, we have demonstrated a scheme for electrical injection in microrings in thin III-nitride epilayers

on silicon that is compatible with microlaser diodes coupled to integrated photonic circuits as it allows for device underetching and the possibility of fabricating side-waveguides with small gaps of less than 100 nm, necessary for efficient coupling in the blue-UV spectral range. We have demonstrated EL of such microrings contacted with a metallic microbridge with 440 mW/cm² output power density at 20 mA.
