Coinfections by multiple Human Papillomaviruses (HPVs) are observed in approximately 6–8% of invasive cervical cancer (ICC) cases worldwide. But neither the presence of persistent HPVs coinfections nor their etiological role in the development of ICC is well understood. Cervical HPVs coinfections have been observed randomly, mostly in women with preneoplastic lesions, and only few studies have globally analyzed ICC cases. Here we explored the HPVs multiple infection patterns in a large worldwide sample of cross-sectional ICC cases. Paraffin-embedded ICC biopsy samples were tested using stringent HPV genotyping. Logistic regression models were used to identify the most likely pairwise HPV types in multiple infections. Multivariate analysis was applied to detect significant HPV coinfection patterns beyond pairwise HPVs comparison. Among 8780 HPV DNA-positive ICC cases worldwide, 6.7% ( $N = 587$ ) contained multiple HPVs. Pairwise analysis revealed that HPV16|74, HPV31|33, HPV31|44, HPV33|44 and HPV45|70 pairs were significantly more frequently found together in multiple infections compared to any other HPV type combination, which supports the occasional role of Alpha-10 LR-HPVs in cervical cancers. In contrast, HPV16|31, HPV16|45, HPV16|51 and HPV18|HPV45 pairs were significantly less frequently found together than with any other HPV pair combination. Multivariate analysis sustained the results and revealed for the first time a distinct coinfection pattern in African ICCs stemming from the clustering of oncogenic HPV51/35/18/52 coinfections in African women. We suggest that the differential geographic HPVs coinfections clustering observed might be compatible with a specific modulation of the natural history/oncogenic potential of particular HPVs multiple infections and warrant monitoring for post-vaccinated.

**Key words:** multiple HPVs infections, invasive cervical cancer, geographic clustering

**What's new?**

While it isn't common for an invasive cervical cancer (ICC) to carry more than one strain of HPV, it does occur. Might these co-infections affect tumor progression or other characteristics of ICC? In this HPV-genotyping study of ICC biopsies worldwide, the authors found several strains that were more likely to occur together. This supports the occasional role of Alpha-10 LR-HPVs in cervical cancers. The study also found a distinct co-infection pattern in African women. These results may be valuable in estimating type competition, and indicate that monitoring even after HPV vaccination is warranted.

**Background**

Among the more than 350 different Papillomaviruses (PVs) identified (<https://pave.niaid.nih.gov>), above 200 are Human Papillomaviruses (HPVs). According to their carcinogenic potential, twelve HPVs are acknowledged as carcinogenic to humans (IARC Group I: HPV16/18/31/33/35/39/45/51/52/56/58/59), while 13 additional HPVs are classified as probably or possibly carcinogenic to humans (IARC Groups 2a and 2b: HPV26/30/34/53/66/67/68/69/70/73/82/85/97). All of them are usually referred to as *high-risk* (HR) HPVs. Two HPVs cannot be classified as to their carcinogenicity to humans (IARC Group 3: HPV6 and 11) and are referred to as *low-risk* (LR) HPVs.<sup>1</sup> Other viruses such as HPV40, 42, 43, 44, 54, and 74 have not been included in any of the IARC Groups but classified by IARC<sup>2</sup> as LR-HPVs. All of these above mentioned HPV types belong to Alphapapillomaviruses within the *Papillomaviridae* family.

HPVs are the most common infectious agents in sexually transmitted infections: above 80% of sexually active women are infected by any HPVs during their lifetime.<sup>3</sup> Fortunately, most of these HPVs infections are transient and cleared by the immune system, while persistent infection with HR-HPVs is a necessary cause for invasive cervical cancer (ICC) development.<sup>4</sup> Coinfections by multiple HPVs are rare in women with normal cytology (between 1% and 3%), common in women with precancerous lesions (between 15% and 41%) and display intermediate levels in HPV-induced ICCs with coinfections being observed between 6% and 8% of the cases.<sup>5</sup> The simultaneous infection by different HPVs seems to have an impact on the natural history of the viral infection. Thus, when compared to single HPV infections, cancerous lesions with multiple HR-HPVs infections contain more oncogenic *E6/E7* HPV mRNA, often from more than one HR-HPV, thus suggesting that HPVs coinfections in precancerous lesions might be more susceptible to carcinogenesis than single infections.<sup>6</sup> Additionally, women coinfecting with at least two different HPVs in the cervix have a higher risk of high-grade cervical lesions, of ICC or of acquiring another HPV infection, compared to those infected with a single type.<sup>7–11</sup>

Current consensus on the etiology of HPVs-related cancers is that individual lesions are associated with individual HPV infections, meaning that lesions, and thus HPVs-induced cancers, are clonal.<sup>12,13</sup> Accordingly, given the large differences in prevalence of HPVs coinfections in lesions of different grade and grade combinations, the etiological role of multiple HPVs

coinfections in the development of virus-induced cancers, if any, still needs to be evaluated. This is especially true given the increasing number of large-scale HPVs vaccination programs currently implemented using bivalent vaccine protective against HPV16/18/31/33/35/45 types, and further inducing herd effects against HPV18/31/33/35 types.<sup>14</sup> In parallel, the 9-valent HPV vaccine is protective against seven HR-HPV types (HPV16/18/31/33/45/52/58) and when these vaccines are widely implemented they will thoroughly change the prevalence pattern of the targeted HR-HPVs infections in humans.

The aim of our study was to explore the prevalence and patterns of HPVs coinfections in a large worldwide cross-sectional study of ICC cases using standardized HPV genotyping methods and applying different statistical models.

**Methods****Study design**

Our study is based on an international retrospective cross-sectional study of presence of HPVs in ICC cases as previously described.<sup>5</sup> The original study included information from 10,575 ICCs and HPV DNA was detected in 85% of the cases. Briefly, paraffin-embedded specimens from consecutive cases (aged 16–97 years) diagnosed with ICC were obtained from histological archives from 38 countries worldwide. Our study and all protocols were approved by both local and ICO ethics committees. After pathological confirmation of primary ICC, HPV DNA detection was performed by PCR with SPF-10 broad-spectrum primers followed by DNA enzyme immunoassay (DEIA) and genotyping with a reverse hybridization line probe assay (LiPA25 SPF10-PCR)—LIPA25 that detects 25 HPV types (HPV6, 11, 16, 18, 31, 33, 34, 35, 39, 40, 42, 43, 44, 45, 51, 52, 53, 54, 56, 58, 66, 68, 70, and 74) (see details in Ref. <sup>5</sup>). Cases showing DEIA positive but LIPA25 negative results (undetermined HPV) were further subjected to Sanger sequencing for HPV identification, as previously described.<sup>5</sup> Special care was given to maintain stringent conditions for HPV type-level detection using the SPF10-PCR LiPA25, a method particularly suitable for HPV genotyping from FFPE specimens.<sup>5,15</sup> To further prevent contaminations the paraffin blocks in our study were processed under strict conditions: four paraffin sections were systematically obtained from each block. First and fourth sections were used for histopathological assessment after hematoxylin and eosin staining, and the second and

third sections were used for HPV DNA detection and genotyping as described.<sup>5</sup> Importantly, a blank paraffin section was cut and processed in-between specimens to control for any carry-over contamination in addition to the standard controls.

### Statistical analyses

ICC cases were classified into single or multiple HPV-infected cases based on the above described genotyping results. Appropriate statistical tests were used to compare the proportion of single and multiple HPV infections by the design variables (age at diagnosis, geographical origin, period of diagnosis and histological type). We estimated prevalence ratio and 95% bootstrapped-confidence interval of single/multiple (S/M) infections for each individual HPV. Unconditional logistic regression models were used to estimate association between demographic and clinical characteristic of the cases, probability of multiple infections, and to identify pairwise coinfections of HPVs that were more likely to be detected together compared to being in combination with any other HPV in multiple infections. To simultaneously estimate the possible associations beyond pairwise HPVs comparison among multiple HPV infected ICCs collected worldwide, we fitted the histological type, period of diagnosis and geographical origin of the sample into our generalized linear model (GLM) of the multivariate HPVs multiple infections dataset.<sup>16</sup> Further, univariate tests for each HPV in coinfecting ICCs were implemented within multivariate analysis to estimate whether there were type-specific differences in HPV coinfection distribution by histology, period of diagnosis or geographic origin. The observed pairwise and composition level HPVs coinfection pattern differences were visualized using network plots constructed with *igraph* R package (R Core Team, <http://www.R-project.org/>). Classification and regression trees (CART) analyses<sup>17</sup> were performed using the *rpart* R package to estimate and visualize the possible HPVs coinfection patterns beyond pairwise HPVs comparison, accounting for age at diagnosis, histology, period of diagnosis and geographic origin of the cases. In practice, CART analyses use recursive partitioning to structure the data into a series of dichotomous splits, e.g. presence or absence of each HPV type and other demographic variables, to create a decision tree with the goal of correctly classifying clusters of the above mentioned interacting variables, for example, HPV16 or HPV18 coinfecting ICCs. Each independent variable is examined and a split is introduced to maximize the sensitivity and specificity, calculated using the predicted probability from the multivariable logistic regression of the classification, and resulting in a decision tree.<sup>17</sup> All regression models were adjusted by the design variables and Bonferroni's correction was implemented in pairwise analyses to control for multiple comparisons. All statistical tests were two-sided and rejecting the null hypothesis was set at a *p* value of less than 0.05. Analyses were carried out with Stata software (Release 13, StataCorp, USA) except otherwise specified.

## Results

### Demographic characteristics of the ICCs

From the 10,575 ICCs previously reported,<sup>5</sup> we excluded the ICC cases with a negative HPV DNA test (*n* = 1598) and cases containing DNA from undetermined HPV further tested with Sanger sequencing (*n* = 197). Thus, the dataset used in our study contained 8780 ICC HPV-positive cases, most of them (91.8%; *N* = 8064) histologically diagnosed as squamous cell carcinomas (SCCs, Table 1). The final dataset of HPV-positive ICC cases consisted of women with a mean age of 51 years (range 17–97) at diagnosis and 23.1% recruited from Europe, 39.6% from the Americas, 31.3% from Asia including Oceania, and 6% from Africa (Table 1). Since infection with other pathogens, notably *Human Immunodeficiency Virus*, could have an impact on age at ICC onset, we verified that the mean age at ICC diagnosis exclusively for African women did not differ from that for women outside Africa (*p* = 0.240, data not shown). Most (*n* = 8193) HPV-positive ICC cases showed the presence of a single HPV, and in 83.8% (*N* = 492) of the cases with multiple infections only two distinct HPVs were detected (Supporting Information Fig. S1). Logistic regression analysis among all ICCs showed prevalence differences between single and multiple HPVs infected ICCs by geographic origin and by period of diagnosis (Table 1). By geographic region, prevalence of multiple HPVs infections was consistently about three-fold less frequent (*p* < 0.001) among women from Europe (0.36 [95% CI: 0.27–0.49]), Asia (0.31 [95% CI: 0.23–0.42]) or the Americas (0.36 [95% CI: 0.27–0.49]) compared to women from Africa (Table 1). Stratification of the African ICC cases revealed that 41.7% were from Mozambique, 30.1% from Nigeria, 19.6% from Uganda and 8.5% from Algeria (data not shown). Cases diagnosed between 1990 and 2009 showed 7.3% prevalence of multiple infections, 1.32-fold (95%CI: 1.08–1.60) higher than ICCs diagnosed between 1940 and 1989 (5.8% prevalence) (Table 1). However the difference in prevalence for multiple HPVs infections was not significant when stratifying ICCs into cases collected before and after 2000 (results not shown).

### HPV type-specific distribution

HPV type-specific distribution in ICCs is presented in Figure 1. With 61.9% (*N* = 5432) prevalence, HPV16 was the most frequent HPV, followed by HPV18 (11.1% prevalence; *N* = 977) and HPV45 (6.7% prevalence; *N* = 585). Their respective contributions in coinfecting ICCs were also the highest: HPV16, 58.4% (*N* = 343), HPV18, 21.0% (*N* = 123); and HPV45, 18.9% (*N* = 111) (Supporting Information Table S2). According to viral taxonomy, the Alpha-9 HPVs (which include HPV16) were involved in 86.5% (*N* = 506) of the coinfecting ICCs, while Alpha-7 HPVs (which include HPV18) were involved in 44.6% (*N* = 262) of the coinfecting ICC cases (see also Fig. 1).

Prevalence of single and multiple HPVs infections in ICC cases along with the patient characteristics, stratified by HR- and LR-HPVs, is given in Supporting Information Table S1. Among ICCs with multiple infections ( $n = 587$ ), 76.0% were exclusively infected with HR-HPVs while only two cases were exclusively infected with LR-HPVs (HPV54|74 and HPV6|53|66). The remaining 23.7% of the multiple infected ICC cases showed a combination of HR- and LR-HPVs. The corresponding values

for ICCs with single infections were 99.5% ( $N = 8149$ ) for only HR-HPVs and 0.5% ( $N = 44$ ) for only LR-HPVs (Supporting Information Table S1). Altogether, six (HPV16/18/31/33/35/45) and seven (HPV16/18/31/33/45/52/58) HR-HPVs covered/cross-protected by the 2- and 9-valent HPV vaccines, accounted for respectively 87.9% and 90.9% of the single-infected ICC cases and were present in 92.0% and 95.9% of the multiple HPV coinfecting ICCs.

**Figure 1.** HPV type-specific prevalence among all single HPV type infected ICCs ( $n = 8193$ ), and exclusively among multiple HPVs infected ICCs ( $N = 587$ ). Abbreviations: HPV, Human papillomavirus; Taxonomy grouping based on ICTV (<http://www.ictvonline.org>) and visualized with gray color. [Color figure can be viewed at [wileyonlinelibrary.com](http://wileyonlinelibrary.com)]

Prevalence of HPVs in single and multiple HPVs infections as well as S/M prevalence ratio are shown in Supporting Information Table S2. Virtually all HR-HPVs, except HPV66 and HPV70, showed S/M prevalence ratios above one indicating a higher prevalence in single than in multiple infections. In contrast, all LR-HPVs (except HPV42) and particularly Alpha-10 LR-HPVs showed S/M prevalence ratios below one, indicating a higher prevalence in multiple than in single infections.

### HPV coinfection pattern analysis

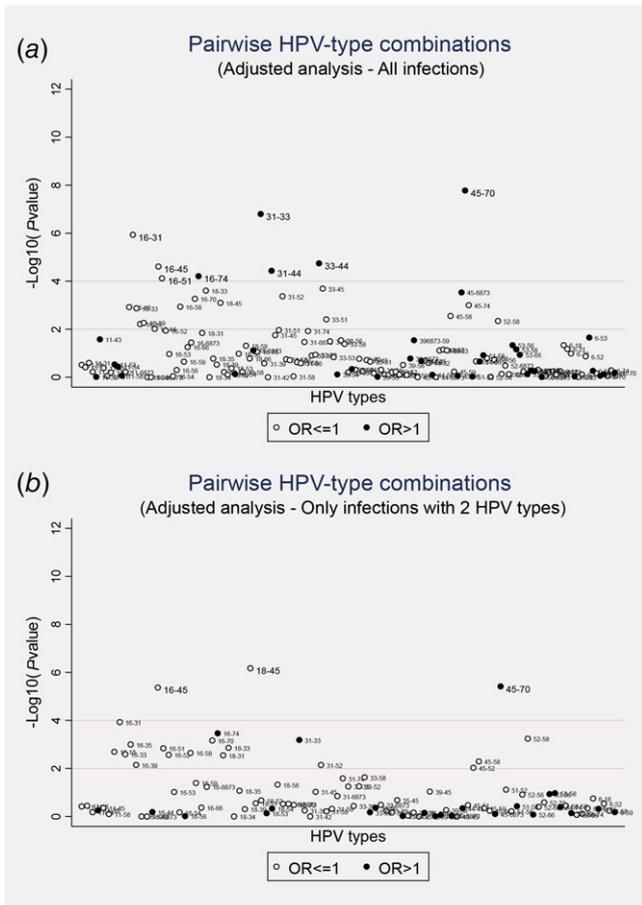

Among all HPVs pairwise combinations detected in ICCs with multiple infections, the prevalence of eight HPV pairs was significantly different from expected by chance: HPV16|74, HPV31|33, HPV31|44, HPV33|44 and HPV45|70 pairs were more likely to be detected together than with any other HPV type, while HPV16|31, HPV16|45 and HPV16|51 pairs were less likely to be detected together compared to other HPVs (Fig. 2a). Restricting the analysis to ICCs infected only with two HPVs revealed that the HPV45|70 combination was more likely and HPV16|45 and HPV18|45 less likely to be detected together compared to any other combination of HPV types (Fig. 2b).

To explore individual viral prevalence differences in ICCs with multiple HPVs infections beyond pairwise analysis, we

performed a multivariate analysis. A significant difference in HPVs composition by geographic origin [likelihood ratio test (LRT) 201.24,  $p = 0.001$ ], by histology (LRT 58.604,  $p = 0.001$ ) and by period of diagnosis (LRT 43.35,  $p = 0.008$ ) was observed (Table 2). A univariate test applied to the multivariate analysis showed a significant virus-specific level difference by histology for HPV31 and by period of diagnosis for HPV74 (Table 2). Furthermore, seven HR-HPVs (HPV18, HPV35, HPV51, HPV52, HPV56, HPV58 and HPV74; Table 2) showed significant or nearly significant coinfection prevalence differences by geography. Accordingly, crude prevalence estimates of the above listed seven HR-HPVs in coinfecting ICCs from Africa were either about two-fold higher, or at least five-fold lower than in any other world region (Table 2). In agreement, stratifying by histology and restricting the multivariate analysis on the SCC cases showed significant HPV coinfection pattern differences by period of diagnosis (LRT 41.60,  $p = 0.012$ ) and by geographic origin (LRT 193.59,  $p = 0.001$ ). Univariate test revealed also significant prevalence differences by period of diagnosis for HPV74 and by geography for five HR-HPVs (Supporting Information Table S3). HPV type-specific networks shown in Figure 3 stratified by geographic origin visualize the multiple HPVs coinfection combinations observed and more importantly, the significant higher frequency of HPV18, HPV35, HPV51 and

HPV52 present in multiple infections in samples from Africa compared to samples outside Africa. The HPV pairs identified with significantly different pairwise coinfections by logistic regression are also visualized in Figure 3.

Finally, two different recursive partitioning analyses were performed to explore the appearance of HPV's coinfections in ICCs with either HPV16 (Fig. 4) or HPV18 (Supporting Information Fig. S2) and accounting for age at diagnosis, geographic origin and period of diagnosis of the cases. First CART analysis searched for a homogenous split of the data on the chosen variable (i.e. HPV16) and the subsequent best splits among all variables that partitioned the data in each step into further most homogenous subgroups, accounting also for age at diagnosis, period of diagnosis and geographic origin of the cases. The predicted probabilities (PP) for each split for other HPV's occurring with HPV16 (PP = 58.4% [95%CI: 54.3–62.5], Fig. 4) or HPV18 (PP = 21.0%, Supporting Information Fig. S2) were presented. Second and third most likely

**Figure 2.** Logistic regression analysis *p* values of the pairwise comparisons (a) among all HPV coinfections and (b) among cases only with two HPV type coinfections, and adjusted for age, period of diagnosis and geography. Abbreviations, OR, Odds ratio, lines indicate  $-\log_{10}(p \text{ value}) = 2$  and Bonferroni's corrected threshold for 2 HPV types co-occurrence  $-\log_{10}(0.01/146) = 4$ . [Color figure can be viewed at wileyonlinelibrary.com]

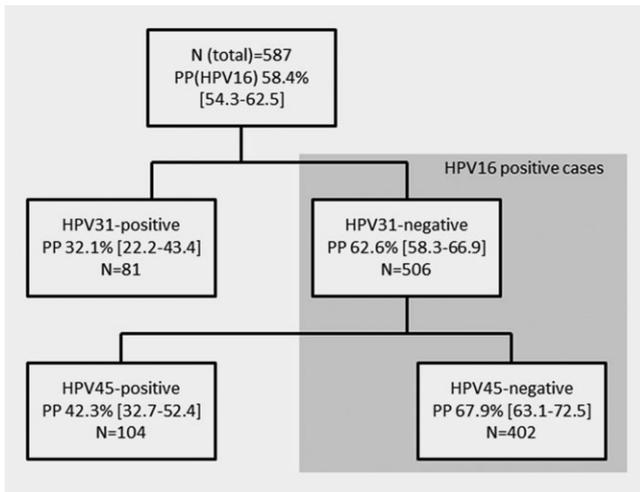

**Figure 3.** Visualization of the coinfection patterns among all 587 multiple HPV's infected ICCs, and stratified by geographical origin of the samples. Nodes are numbered by the corresponding HPV type and node size is proportional to the observed HPV type prevalence in coinfecting ICCs. Node colors represent the following: HPV types with significantly higher prevalence in coinfecting ICCs in Africa compared to other world regions are shown in orange. HPV types with significantly lower prevalence in coinfecting ICCs in Africa compared to other world regions are shown in blue. Each line represents the coinfection observed between the two HPV types with a width proportional to the total number of these coinfections observed in this study. Orange color of the coinfection line indicated that the two HPV types were more likely to be detected as coinfections and blue color indicated that the two HPV types were less likely to be detected as coinfections compared with any other HPV's coinfecting ICCs. [Color figure can be viewed at wileyonlinelibrary.com]

splits suggest respectively a major exclusion of HPV31 (PP = 62.6% [95%CI: 58.3–66.9]) and of HPV45 (PP = 67.9% [95% CI: 63.1–72.5]) from HPV16-related coinfections. In parallel, the two major exclusion variables from HPV18 coinfections and their predicted probabilities were non-African cases (PP = 39.6%) and HPV45 coinfection exclusion (PP = 47.4%) (Supporting Information Fig. S2).

**Discussion**

In our study, we describe distinct clustering patterns of different HPV's detected in multiple HPV's infections in the largest available global collection of ICCs in unvaccinated women. Our results confirm that the simultaneous detection of different HPV's in ICCs is rare albeit far from negligible (6.7% in our dataset, *N* = 8780). The association patterns identified suggest further that the clustering of multiple HPV's in ICCs is not random. Our most relevant findings were a significant

**Figure 4.** Classification and regression tree (CART) of the HPV16 coinfections. On top of the tree is shown the basal node containing the entire data set with the predicted probability of HPV16 coinfections, and also visualized in gray color. Two subsequent splits between HPV16 - HPV31, and between HPV16 - HPV45 suggest a likely competition between the types among the HPV coinfecting ICCs. Number of cases (N) in each node and the corresponding predicted probabilities (PP) in percentages [95% confidence interval].

causal/coincidental infection of LR-HPV types 44 or 74 in ICCs in combination with HR-HPV types 16, 31 or 33, and a marked geographic clustering of particular oncogenic HPV types 51, 35, 18 and 52 (in descending significance) in multiple HPVs infected cervical cancers in African women compared to women outside Africa. A number of studies have previously communicated that clustering patterns observed among HPVs do not always occur at random in multiple infections detected in normal cytology, in cervical precancerous lesions or in cancer lesions.<sup>7,18–22</sup> Nevertheless, our results

disagree with the previous studies, which suggest that the observed nonrandom HPVs clustering in multiple HPV infections is mainly due to technical biases originating from the HPV genotyping methods.<sup>23</sup>

The existence of genuine nonrandom association pattern of HPVs in multiple infections is elusive, and identifying and excluding technology-driven biases is not a simple task. Nevertheless, a public health concern is that HPVs coinfections may have a role in ICCs development not only among unvaccinated<sup>24</sup> but also among HPV vaccinated women.<sup>25</sup> The rationale is that due to ecological competition between HPV types, the HPV vaccine implementation may further clear the ecological niche for the nonvaccine-targeted oncogenic HPVs.<sup>25–27</sup> Particularly, some HPVs such as HPV39 and HPV51 not included in the vaccine formulations have previously shown increase in prevalence after vaccination suggesting the possibility of type replacement.<sup>25,26</sup> However, thus far, competition between HPV types, which is the prerequisite for HPV type replacement, has not been persistently observed among unvaccinated<sup>7,18,28,29</sup> or vaccinated populations.<sup>25–27</sup>

**HPVs coinfection prevalence**

Here in our study we describe known as well as novel patterns of nonrandom HPVs clustering in global ICC cases, identified using a single well established HPV detection and genotyping technique. For clarity, it is important to remind that the current consensus of ICC etiology follows the logic of superinfection exclusion,<sup>30</sup> with a subsequent clonal origin of HPV-induced lesions indicating that a single HPV virus contributes to the development of a single ICC lesion.<sup>12,13</sup> This is to say, that the presence of DNA from two or more HPV types in an ICC sample does not necessarily mean that the different HPVs detected, actually contribute to the cancer development. Previously, techniques of laser capture microdissection (LCM) have been successfully used to affirm the likely involvement of

**Table 2.** Multivariate analysis of all 25 HPV types available among coinfecting ICCs, and HPV type-specific prevalence distribution for eight HPV types showing significant clustering by histology, period of diagnosis or geographic origin of the samples

ICCs	Histology		Period of diagnosis		Geographic origin		Geographic origin			
	LRT	p value	LRT	p value	LRT	p value	Prevalence among HPV coinfecting ICCs

HPV types in descending order regarding the LRT values by geographic origin.

causal or coincidental HPVs with particular lesion component in multiple HPVs infected cases, further supporting the hypothesis of clonal origin of HPV-induced cervical cancers.<sup>13,31</sup>

In ICC cases worldwide, we did not observe significant differences in HPVs coinfection prevalence between the age groups at diagnosis. These results seem to be in contrast to the studies reporting higher prevalence of multiple HPVs infections in sexually active adolescents and in young women,<sup>19,24,32</sup> and thus, our results might actually indicate that regardless of the sexual risk-taking behavior coinfection by multiple HPVs may be a risk factor for malignant cervical transformations. Interestingly however, a recent study suggests reduced HPV-driven carcinogenesis in cases of coinfection with oncogenic HPV types from the same papillomavirus species among HIV-infected patients.<sup>33</sup> This was interpreted as an evidence of natural cross-protection against HPV-induced carcinogenesis by multiple HPV infections from the same HPV species group.<sup>22,33,34</sup> Nonetheless, we did observe that HPVs coinfection prevalence was consistently about three-fold higher in ICCs from Africa compared to the rest of the world. One explanation could be concomitant HIV infection which may increase the prevalence of multiple HPVs coinfections.<sup>35</sup> Information on the sexual risk-taking behavior or HIV status was, unfortunately, not available for our ICC cases but the corresponding population estimates by Bruni and colleagues<sup>36</sup> showed a relatively high prevalence of HIV infections among women in Mozambique, Uganda and Nigeria (11.3%, 7.2 and 3.7%, respectively). Thus, the larger fraction of women infected by HIV in these African populations compared to other populations worldwide may partly play a role in the higher presence of multiple HPVs infections also in our African ICC cases.

#### DNA degradation

Despite using a highly sensitive PCR based method for HPV genotyping (based on a 65 base pairs amplicon), we detected a minor 1.3-fold higher prevalence of coinfections in the more recently diagnosed ICC cases (between 1990 and 2009) than in older cases (between 1940 and 1989), but the difference was not significant when ICCs were stratified for cases collected before and after 2000 (results not shown), and these results were further supported by our multivariate analysis showing significance only for the 1990 stratification. Essentially, most paraffin embedded samples are initially fixed in formalin-containing solution, which reacts with the lateral amino groups in proteins and DNA, and thus, complicates the DNA isolation from FFPE samples.<sup>37</sup> More importantly, the aldehyde in the formalin is unstable if unbuffered (used in most historical FFPE samples at least before the 1990s<sup>37</sup>), and disproportionate rendering methanol and formic acid, causing extra fragmentation of the sample DNA. In short, we cannot completely rule out the possible effect of additional DNA degradation stemming from older tissue-fixation protocols, as described by Gilbert and colleagues.<sup>37</sup> Notwithstanding, we

estimate that older tissue-fixation protocol related DNA degradation plays a minor role (e.g. lowest LRT estimated for period of diagnosis) in explaining the higher prevalence of multiple HPVs infections in cases collected since 1990 compared to the older ICC cases.

#### HPV type-specific clustering

At pairwise association level, we found a significant causal or coincidental infection of LR-HPV types 44 or 74 in combination with HR-HPV types 16, 31 or 33 in global ICCs. Moreover, all Alpha-10 LR-HPVs (HPV6/11/44/74) showed a markedly higher prevalence in multiple HPV type infections compared to single HPV type infected ICCs.

Altogether, we identified five positive and four negative significant associations between HPV types among the multiple infected ICCs. Three of the five positive associations were novel (i.e. HPV16|74, HPV31|44 and HPV33|44) while association between Alpha-9 species HPV31 and HPV33 or between Alpha-7 species HPV45 and HPV70 had also been previously estimated.<sup>38</sup> Current epidemiological research supports the double etiological origin for HPV-induced cervical lesions: LR-HPVs, mainly HPV6 and HPV11, mostly leading to benign low-grade squamous intraepithelial lesions (LSILs), and oncogenic HR-HPVs, if persistent, mostly leading to high-grade SILs, and considered cervical cancer precursor lesions. Nonetheless, low-risk HPVs such as HPV6, 11 and 44 from the Alpha-10 species have previously been occasionally associated with causal and coincidental infections in anogenital cancers.<sup>31,39</sup> In addition, previous studies have also shown that a fraction of low-grade cervical SILs may also harbor components of HSIL or carcinoma often associated with independent HPVs infections, thus following the logic of “one-virus one-lesion”.<sup>13,40</sup> In agreement, our results match well the logic of an essentially clonal origin of HPV-related lesions and support the occasional causal and/or coincidental role of low-risk Alpha-10 HPVs in cervical cancer development.

Theoretical models have predicted natural competition between HPV types,<sup>28,41</sup> such as between types from the same HPV species group, and here we observed four significant negative pairwise HPV type associations: HPV16|HPV31 and HPV18|HPV45 pairs within the same species, and HPV16|HPV45 and HPV16|HPV51 pairs with longer pairwise phylogenetic distance between the types. Furthermore, our multivariate CART analysis beyond pairwise HPVs estimation revealed the same patterns of negative association between three of the HPV pairs, and thus, sustained the idea of possible competition or antagonistic interaction between these types. Novel negative association between HPV16|HPV45 types and two also previously reported negative associations, namely HPV16|HPV31 and HPV18|HPV45 pairs within the same species group.<sup>28,42</sup> Notably, antagonistic interactions between HPV6/11 and HPV16, and between HPV6 and HPV31 types, earlier infections with the LR-HPVs protecting against cervical cancer risk associated with the latter HR-HPV

infections have been documented,<sup>43,44</sup> and indirectly fit with our observations on less likely coinfections with HPV16 and 31, and HPV18 and 45. Taken together, the assumption that HPV types within the same species group, such as Alpha-7 (HPV18, 39, 45, 59, 68, 70 and 85) or Alpha-9 (HPV16, 31, 33, 35, 52, 58 and 67), compete with one another<sup>28,42</sup> is not clear as we also observed positive pairwise HPV type associations for HPV31|33 and HPV45|70 pairs.

Our most relevant finding is the distinct geographic clustering of HPVs multiple infections in ICCs among women from Africa compared to women outside Africa. Particularly, a significant geographic clustering of oncogenic HPV types 51, 35, 18 and 52 in multiple infections was observed in African women. That is, beyond pairwise level association and exclusively among the HPVs coinfecting ICCs, we identify for the first time seven (i.e. HPV51, HPV35, HPV18, HPV74, HPV58, HPV52, HPV56) geographic clustering patterns for specific HPVs, in descending significance. Earlier studies regarding worldwide HPV genotype attribution in ICCs have described particular type-specific geographic structure, namely higher prevalence for HPV16, HPV18 and HPV45 in African populations, and a higher prevalence for HPV52 and HPV58 types in Asian populations compared to other world regions.<sup>5,45,46</sup> In agreement, our multivariate analysis among the coinfecting ICCs or only among the coinfecting SCC cases demonstrated the significantly higher prevalence clustering of HPV18 in Africa and HPV58 in Asia. In contrast, HPV52 showed marginally significant higher geographic clustering among African women with intermediate prevalence in Asia while HPV16 or HPV45 coinfection prevalence values did not reveal any geographical structure. Most interestingly the observed patterns of geographic clustering of HPVs among the coinfecting ICCs practically originate from differences between Africa and other world regions. As such, the prevalence of HPV51, HPV35, HPV18 and HPV52 types were about two-fold higher in African multiple infected ICCs, while prevalence of HPV56, HPV58 and HPV74 was either absent or at least two-fold lower in African ICCs compared to any other world region. Most importantly, the highest LRT values observed in our multivariate analysis were both the geographic clustering of multiple infections in general and at type level the geographic clustering of oncogenic HPV51, HPV35, HPV18 and HPV52 types in African multiple infected ICCs. Simultaneously, a recent community-randomized clinical trial data from Finnish population showed an increase of HPV51 and HPV52 in multiple HPVs infected women post-vaccinated.<sup>25</sup> However, within a public health perspective earlier studies have shown that although HPV51 is classified as possibly/probably oncogenic by the IARC, it presents a low oncogenic potential to cause ICCs and is commonly more prevalent in low-grade cervical lesions.<sup>47</sup>

In addition, a minor clustering of HPVs by histological type was also observed among the HPV coinfecting ICCs. A significantly higher contribution of HPV31 was observed in SCCs compared to other type of ICCs, mostly

adenocarcinomas (ADC) or mixed adenosquamous carcinomas (ADSC). Previous studies have already reported these HPV type distribution differences between single infected cervical SCCs and ADCs/ADSCs,<sup>5,48</sup> and our results among multiple HPV coinfecting ICCs further sustain the results.

Nevertheless, and despite the large worldwide cross-sectional sampling of ICC cases and the standardized HPV genotyping methodology used, our study suffers from certain limitations. Firstly, detection of more than one HPV type or variant in a sample is not enough to assign causality of the multiple HPVs with the particular lesion, in this case, the ICC. Secondly, further cohort studies and use of other biomarkers providing biological activity of particular HPVs such as mRNA or p16INK4a expression, and with new statistical models are needed to better disentangle the role of multiple HPVs infections in the etiology of cervical cancer, especially in the post-HPV-vaccinated environment. Thirdly, a better characterization of the patients' genetic background, possible HIV infections, heterogeneous ICCs biopsy material and detection method cross-validation is needed to confirm the potential role of multiple HPVs infections in ICCs. Lastly, the detection and ultimately the likely role of multiple HPVs infections at HPV variant level has only recently been verified thanks to the next-generation sequencing applied to HPV genotyping,<sup>49</sup> but within host HPV type-level variation is beyond the scope of our study.

Our genotyping strategy was based on the differential hybridization of very short PCR products, and as such, we cannot completely rule out the possibility that some of the observed clustering of multiple HPV type coinfections in our study is not partly due to PCR and hybridization biases and directional cross-detection of multiple HPVs. However, several lines of evidence argue against that the possible technology-based cross-detection biases are the main explanation for the HPVs clustering patterns observed. First, it has been previously shown that the SPF10-PCR LiPA25 methodology is more sensitive and less prone to overemphasize multiple HPVs infections than other PCR-based methods.<sup>15</sup> Second, it is unlikely that the observed differential HPVs clustering after histological or geographical stratification exclusively originates from unspecific genotyping, as it would imply that such hybridization biases are both histology and geography dependent. Third, we found the worldwide nonrandom clustering of different HR-HPVs in coinfecting ICCs at two different analysis depths, at pairwise and at multivariate level as described above.

Taken together, HPVs coinfection patterns are rare in ICCs, and thus difficult to study at population-level. In our study, however, we provide robust and worldwide estimations on the proportion of single and multiple HPV type infected ICCs and reveal HPVs pairwise combinations significantly deviating from the null expectation. Further, we identified for the first time beyond pairwise analysis a distinct coinfection pattern in African ICCs compared to any other world region.

Our results suggest that this differential clustering of HPV type combinations in ICCs after stratifying by histological presentation and geographical origin might be compatible with a specific modulation of the natural history of the infection and/or of the oncogenic potential of particular HPVs multiple infections. Finally, although our results may be valuable in estimating competition between nonvaccine HPV types and warrant monitoring for post-vaccinated, it should be emphasized that clustering of multiple HPVs infections are marginal in ICCs with likely only a minor public health importance, and mostly among high sexual risk-taking behavior population groups.
