Abstract—Non-tracking planar concentrators are a low-cost method of increasing the performance of traditional solar photovoltaic (PV) systems. This paper presents new methodologies for properly modeling this type of system design and experimental results using a bi-directional reflectance function (BDRF) of non-ideal surfaces rather than traditional geometric optics. This methodology allows for the evaluation and optimization of specular and non-specular reflectors in planar concentration systems. In addition, an outdoor system has been shown to improve energy yield by 45% for a traditional flat glass module and by 40% for a prismatic glass crystalline silicon module when compared to a control module at the same orientation. When compared to a control module set at the optimal tilt angle for this region, the energy improvement is 18% for both system. Simulations show that a maximum increase of 30% is achievable for an optimized system located in Kingston, ON using a reflector with specular reflection and an integrated hemispherical reflectance of 80%. This validated model can be used to optimize reflector topology to identify the potential for increased energy harvest from both existing PV and new-build PV assets.

Index Terms—planar concentrator, low concentration, crystal silicon, optics, BDRF, reflectors, booster mirrors, photovoltaic, photovoltaic system

NOMENCLATURE

G_{diff}	Diffuse irradiation (W/m^2)
G_{DNI}	Direct normal irradiation (W/m^2)
G_p	DNI projected onto the vertical plane (W/m^2)
G_m^i	Irradiance on the surface of the module due to reflection (W/m^2)
E_r^i	Energy incident on the reflector surface (W)
E_r^o	Energy leaving the reflector surface, per degree (W/θ)
E_m^i	Energy incident on the surface of the module (W)
T_a	Ambient temperature ($^{\circ}C$)
A_m	Module Area assuming a unit depth ($\int dz = 1$) (m^2)
AR	Area ratio of illuminated to non-illuminated module area
F_{rm}	View factor between module and reflector
x	Dimension along the module (m)
y	Dimension along the reflector (m)
y	Dimension orthogonal to x and y (m)
r	Direct distance between dx and dy (m)
w_{refl}	Reflector length (m)

w_{mod}	module length (m)
L'	Distance of reflector image along x axis (m)
L_m	height of the point of intersection of the reflector image to the module edge (m)
W_{az}	Distance from reflector edge to top of the reflector image in the z plane
θ	Angle between outgoing ray and reflector surface normal
θ'	Angle between incoming ray and reflector surface normal
β	Angle between reflected ray and module surface normal
γ_{array}	Surface azimuth, 0° south
γ_{sun}	Sun azimuth, 0° south
α_p	Solar Elevation angle
α_p	Solar Profile angle
ω	Module angle
ω_{incl}	Included angle between module and reflector
ϕ	Reflector angle
ϵ	Half angle between θ and θ'
m	Beckmann surface roughness
ρ	Hemispherical reflectance

I. INTRODUCTION

Solar photovoltaic (PV) systems are a rapidly expanding sustainable renewable energy market, and will play a large role in the future sustainable energy mix [1], [2]. Currently, commercial and utility scale PV installations are predominately arranged in multiple parallel rows of flat modules, which are aligned towards the mean maximum solar intensity [3].

Modules must be installed with a setback from the row in front of it, to reduce inter-row shading losses and allow maintenance access. The spacing of these rows is highly dependent on the latitude of the solar array, land availability, and economic constraints which determine the economic performance of a system [4]. Typically, the row spacing is designed to reduce inter-row shading losses that occur in the early morning and late afternoon; however, this arrangement leaves the spaces between rows illuminated during the periods of highest solar resource which is around solar noon [5].

Previous work has investigated the application of planar reflectors for both solar thermal and photovoltaic applications. Much of the early work on planar concentration was focused on the improvement of winter time yields for solar thermal systems [6]–[9]. Some studies found that the optimal orientation for this at high latitudes was a vertical collector with a horizontal reflector [8]. A large body of literature has

also looked at various ray tracing models for estimating the increase in irradiation from a given reflector geometry [8]–[18]. Of these models, there are some that account for diffuse reflectors that utilize a combined view factor and specular reflectance model [11], [13], [14], some that analyze a two dimensional specular reflectance model [18], and some that include experimental results [7], [10], [18], [19]

Currently, planar reflectors are utilized in district heating solar thermal plants in Sweden and Denmark [5], and have been shown experimentally to increase the thermal energy collection at sites of 60°N latitudes by around 30% [18] compared to a module at the same tilt angle of 45° . It has been proposed that the introduction of non-specular corrugated booster reflectors may further increase the outputs of these fields by up to 8% [5] and the Bi Directional Reflectance Function (BDRF) of these corrugated materials also have been characterized [12].

There are limited examples of experimental studies that address the specific effects of low-level concentration on PV system losses, and recently a study was undertaken to identify these additional loss mechanisms [20].

Unfortunately, though the technical feasibility of these systems has been shown, at the time of publication only one entity has commercialized a comparable system for PV applications [21], and because of assumptions made in the design of the system, specialized parallel modules must be utilized with this system, which tend to increase the costs of the system.

In order to investigate the potential implementation of non-tracking planar concentration PV systems for conventional low-cost PV modules, this study: 1) develops and validates a model using the concept of the BDRF of non ideal surfaces rather than geometric optics and 2) experimentally investigates systems in an outdoor test site in Kingston, Ontario utilizing commercially available crystalline silicon PV modules. The proposed model integrates previous work which analytically investigated the module temperature increases, diode loading, and angle of incidence effects. The outputs of this model are used to perform a sensitivity analysis which identifies important factors in the design of low-level concentration systems.

This chapter is derived from a technical paper submitted to the IEEE Photovoltaics Specialists Conference (PVSC) of the same name [22] study expands on this work through: 1) refining and further validating a model using the concept of the BDRF of non ideal surfaces rather than geometric optics, 2) undertaking laboratory scatterometry and solar simulator testing to compliment experimental data collected at an outdoor test site in Kingston, Ontario 3) utilizing the validated model to perform a sensitivity analysis which identifies important factors in the design of low-level concentration systems. It should be noted that the original reported boost of 35 % for a prismatic glass module was erroneous, and upon further analysis it was found that the boost is in-fact 40 %

II. EXPERIMENTAL APPARATUS

A. Outdoors testing

A $6\text{m} \times 2.5\text{m}$ planar concentrator was installed at the Open Solar Outdoors Test Field (OSOTF) in Kingston, Ontario ($44^\circ 14' 0''\text{N}$, $76^\circ 30' 0''\text{W}$) in the fall of 2011 [23]. Two stacks of landscape crystalline silicon (c-Si) PV modules were arranged in front of the wide planar reflector, and their actual locations with respect to the reflector are shown in Figure 1. One stack had modules with a prismatic glass front sheet, and the other stack had traditional flat glass modules. Each module had a length of 1m in the plane shown in Figure 2 and the reflector had a length of 2.5m in the same plane. Figure 2 shows the two dimensional domain used for the analysis and modeling of the system, and is described in detail in section III-A.

Fig. 1: Plan view of installed system

The tilt angles of the surfaces from horizontal were initially $\phi = 20^\circ$ and $\omega = 57^\circ$, see Figure 2. After July, 2013 the reflector angle, ϕ was changed to 15° to test the sensitivity of the proposed model to changes in input conditions. These values were chosen based on an initial optimization of the system using the methodology outlined in [20].

A set of control modules with no reflectors were installed at the same module tilt angle, and at a tilt angle of 30° to closely match the optimal tilt angle for the region. This is slightly different than the overall optimal angle for the Kingston region of 35° due to mechanical limitations of the racks used in the study. Based on analysis using the PVSYS modeling tool, the difference in irradiance on a surface at 30° in the Kingston region is less than 0.4%.

Meteorological measurements were made with two CMP 22 pyranometers, which measured global horizontal and diffuse horizontal irradiation, and temperature and wind speed measurements were taken at the site. The modules were monitored

for short-circuit current (I_{sc}) and for temperature at the top and bottom of the module.

Fig. 2: Schematic of the modeled domain, all dimensions are in the plane normal to the surface which they are measuring.

The concentration system was installed in November 2011, and had two forms of reflector installed: i) semi-diffuse, flexible reflector made of an aluminized PET laminate, (Foylon), and used until July, 2012, and ii) a specular aluminized PET reflector (mylar), which was installed for the remainder of the test period. The Mylar and Foylon reflectors had a hemispherical reflectivity of approximately 73% and 84%, respectively on installation. After 2 years of exposure, the hemispherical reflectivity of the Mylar and Foylon decreased to 60% and 65%, respectively. It should be noted that both these films do not display good long-term weathering characteristics and should not be used for long term system analysis or PV system augmentation. The modules and reflector were cleaned of any major soiling and organic depositions when they were observed.

B. Scatterometry

A J.A Wollam variable angle spectroscopic ellipsometer (VASE) was utilized to performed scatterometry on both reflector materials. The reflector samples were adhered to a standard glass slide, which was placed on the rotating sample mount of the VASE. Scattered irradiance was measured using the collimated receiver from angles of -10° to 10° degrees from specular, and at wavelengths of 300nm-1000nm in increments of 100nm. The sample was rotated with respect to the light source, and scatterometry was measured at angles of incidence relative to the reflector surface of 75° , 60° , 30° , and 15° . The reflectivity at each wavelength was weighted by the quantum efficiency of a c-Si module, in order to derive a spectrally integrated reflectivity. The experimental results are shown normalized by the maximum reflectivity at each incidence angle in Fig 3.

The data is presented in a normalized fashion, as the primary purpose of this dataset is the validation of the use of the normalized Beckmann distribution introduced in section ??, and the derivation of physically representative scattering coefficients. Because the ellipsometer used is highly

Fig. 3: Polar Co-ordinate view of normalized measured scatterometry data for the semi-diffuse and specular reflector.

Fig. 4: Schematic depicting the apparatus utilized to simulate a reflector system under a solar simulator.

collimating, and scattering measurements were taken only in a two dimensional plane, the intensity measurements are not physically representative.

C. Solar simulator testing

A small-scale model of a large scale reflector system was constructed to produce validation data for the proposed reflector model under controlled laboratory conditions. A schematic of the test system utilized is shown in Figure 4.

Irradiance was provided by a class AA solar simulator. The illuminated area projected onto the test apparatus had a visible diameter of 14 cm, however there was significant attenuation at the edges of this projected area. Thus, it was ensured that at all times the sensor and the majority of the reflector were within an area described by a 9cm diameter which maintained a uniform intensity within 3% of the peak area mean, as shown in Figure 5

Tests were performed by setting an included angle between the reflector and sensor, ($\theta_{included}$), and subsequently varying the sensor angle, (θ_{sensor}) from 0° to 90° from the horizontal. This process was repeated for multiple reflector samples, and a summary of the experimental results is shown in Figure 6

Fig. 5: Illustration of the illuminated area projected onto the surface of the test apparatus

Fig. 6: Summary of reflector characteristics for a variety of materials, with an included angle ($\theta_{included}$) of 100° . The sudden rise in output around 15° is due to the top edge of the reflector image reaching the bottom edge of the sensor. The gradual decline in intensity after the peak is due to the dilution of the reflector image as it extends beyond the top of the sensor element, and is also dominated by angle of incidence effects.

III. MODELLING

A reflectance model based on a Bi-Directional Reflectance Function, BRDF, for an isotropic roughened surface is developed here to predict the performance of the reflector system. The model methodology presented in this paper uses the concepts of the BRDF of non-ideal surfaces rather than traditional geometric optics [24], [25]. This methodology allows for the evaluation of non-specular reflectors in planar concentration systems, which has been shown to increase the energy yields from these systems compared to purely specular reflectors. [5], [26]

The BRDF classifies the three dimensional scattering of light from a surface, and is described theoretically by Beckman

and Spizzichino [27]. Recently, BRDF modelling and research has been a focus in the field of computer graphics [24], [28]–[30]. A modified version of the Cook-Torrance model is used in this paper, which is a commonly implemented model capable of simulating nearly specular to highly diffuse and anisotropic surfaces [24], [25]. Here, this BRDF formulation has been modified to ensure energy conservation.

The BRDF defines irradiance that reaches a module as a function of both the angle of incidence (θ') and the angle of viewing (θ) of the light. In the case of a perfectly specular reflector, the BRDF resembles the Dirac function, with a value of 1 when the incident angle equals the outgoing angle ($\theta=\theta'$), and 0 at any other viewing angle. This is the assumption of a ray-tracing concentrator model. However, real surfaces are not perfect specular reflectors and thus reflect light in a distribution as defined by the BRDF of the material, and is a combination of both diffuse and specular reflections.

A. Model Domain

The domain being considered in this model is shown as a function of the representative angles in Fig 2. An integrative approach is taken in the analysis, where the contribution of irradiation to a differential point on the PV module (dx) from each differential scattering element on the reflector (dy) is computed. Thus, an integration is performed along the two principle directions of the array, x and y as shown in Figure 2.

In order to account for the diode topology of a PV module, the model divides each module domain into four distinct sections along the x -coordinate. The minimum irradiance from any of the four domains is taken as the limiting energy incident on the module, and is used to predict the overall energy production of the module.

B. Model Derivation

A set of simplifying assumptions are used:

- 1) The reflector is assumed to be infinite and homogeneous along its length. Therefore reflection is only considered in a two dimensional plane normal to the infinite dimension. NOTE: For the experimental validation of the model, azimuthal effects of the finite reflector were taken into account as described in section III-C.
- 2) The reflector is a broadband reflector, and spectral attenuation is not taken into account.

The major implication of simplifying the domain of the reflector onto two-dimensional geometry is to properly account for the projection of the three-dimensional incident light ray onto the two dimensional domain. This is done using a modified version of the profile angle, α_p equation introduced in [31] and recommended in [32]:

$$\alpha_s = \pi/2 - \text{Zenith} \quad (1)$$

$$\tan(\alpha_p) = \frac{\tan(\alpha_s)}{\cos(\gamma_{sun} - \gamma_{Array})} \quad (2)$$

$$G_p = G_{DNI} \frac{\sin(\alpha_s)}{\sin(\alpha_p)} \quad (3)$$

Where Zenith is the solar zenith angle, α_s is the three dimensional solar elevation angle, γ_{sun} and γ_{array} are the

solar and array azimuth angles, respectively, and α_p is the two-dimensional solar profile angle.

Recalling the model domain that is depicted in Fig 2, Equation 4 shows the radiant intensity [W] that impacts the plane reflector at point dy and to a depth dz . Equation 5 represents the value of reflected radiant intensity per unit depth through a differential angle $[W/\theta]$. Note that the BDRF is normalized such that $\int_0^\pi BDRF d\theta = 1$. Equation 6 shows the radiant intensity per unit depth that strikes the surface of the module. Note that θ is defined in Equation 7 in terms of the angle of incidence of the differential ray onto the surface of the module, β , and the distance the ray has travelled (r).

$$E_r^i = E_p \cos(\theta') dy dz [W] \quad (4)$$

$$E_{refl} = E_r^i BDRF(\theta, \theta') \rho [W/\theta] \quad (5)$$

$$E_m = E_{refl} d\theta [W] \quad (6)$$

$$d\theta = \frac{dy \cos(\beta)}{r} \quad (7)$$

$$BDRF(\theta, \theta') = \frac{r D(\theta, \theta')}{\int_{-\pi/2}^{\pi/2} D(\theta, \theta') d\theta} \quad (8)$$

Equations 4-8 can be combined and integrated along the characteristic dimensions, and divided by the area of the module being analyzed (A_{module}) to obtain the irradiance on the module surface.

$$G_m^i = \frac{G_p \rho}{A_m} \int_0^{L_{sect}} \int_{L_{m,min}}^{L_{m,max}} BDRF(\theta, \theta') \cos(\theta') \frac{\cos(\beta)}{r} dx dy \quad (9)$$

where G_m^i is the irradiance (W/m^2) on the surface of the module, ρ is the specularly constant surface reflectivity, θ' is constant for a given time step, and θ , β , and r are a function of the linear distances along reflector and module, x and y :

$$r = \sqrt{(x^2 + y^2 - 2xy \cos(\phi + \omega - \pi/2))} \quad (10)$$

$$\theta = \pi - \sin^{-1} \left[\frac{r^2 + y^2 - x^2}{2ry} \right] \quad (11)$$

$$\beta = (\pi - \phi - \omega) - \theta \quad (12)$$

and $D(\theta, \theta')$ is given by the Beckmann distribution [27].

$$D(\theta, \theta') = \frac{1}{m^2 \cos^4(\epsilon)} \exp \frac{\cos^2(\epsilon) - 1}{m^2 \cos^2(\epsilon)} \quad (13)$$

$$\epsilon = \theta - \frac{\theta + \theta'}{2} \quad (14)$$

where m is a physical parameter that represents the rms slope of surface roughness on the reflecting surface and generally $m \in [0, 0.5]$. ϵ is the angle from the surface normal of the vector bisecting θ and θ' .

The BDRF of the two surfaces used in this study were measured using the scatterometry techniques described in section II-B. The theoretical approximations for the BDRF using Equation 13 were also calculated for values of $m=0.03$ for the specular reflector and $m=0.07$ for the semi-diffuse reflector, which were found to be the closest match to the

Fig. 7: Comparison of measured scatterometry results from both reflector materials to modelled BDRF distributions for two values of the roughness coefficient (m).

Fig. 8: Illustration showing potential partial illumination of a module by a finite reflector length. South is down.

measured data, and the comparison of the experimental and theoretical values is shown in Fig 7

The diffuse contribution of irradiation was evaluated using the diffuse view factor between the reflector and PV module, F_{rm} , as described by [33].

$$F_{rm} = \frac{R + 1 - (R^2 + 1 - 2 \times R \times \cos(\omega_{incl}))^{\frac{1}{2}}}{2} \quad (15)$$

where R is the ratio of module length to reflector length, and ω_{incl} is the angle between the two surfaces.

C. Azimuthal correction

The 2D model proposed above was modified to account for the illumination effects of finite reflector lengths. It is possible that in the morning and evening, irradiance at high azimuth angles would not illuminate the entire module as shown in Figure 8. This was accounted for by calculating the non-illuminated area of the module during these periods, and adjusting the expected energy output by the calculated area ratio. This is a process similar to the one implemented by Bollentin [17].

The equation proposed by Bollentin utilized was modified to the following:

$$L' = \frac{wrefl}{\sin(2 \times \omega + \phi - \alpha_p) \times \sin(\alpha_p - \omega)} \quad (16)$$

$$W_{az} = -\tan(\gamma) * (L' \times \cos(\omega) + wrefl \times \cos(\phi)) \quad (17)$$

$$L_m = \text{abs}(L' / W_{az} \times W) \quad (18)$$

$$AR = 1 - \left| \frac{.5 \times (L' - L_m) \times \frac{W_{az}}{L'} \times (L' - L_m)}{L' \times wmod} \right| \quad (19)$$

where $L' = L_{mod}$ if $L' > L_{mod}$. The value AR represents the effective area ratio of the area not illuminated by the specular image of the reflection. As a first order approximation, the total irradiance on the surface of the module is given by $G_m^i * AR$ in cases where edge effects are considered.

D. Model Implementation

The BDRF model was run iteratively for the full measured dataset of incoming irradiance and zenith angles, and the dual integration was run at each step. The amount of irradiation that directly impacts the module was evaluated using the Perez irradiation translation model [34]. Once the total in-plane irradiation on the face of the module was evaluated, the predicted module output was calculated using the methodologies outlined in [35] using coefficients derived from the control module. Note that only I_{sc} was collected from the modules, and therefore the validation of the model was performed using I_{sc} rather than power. I_{sc} is an excellent predictor of effective irradiance on the plane of the array [35], and is therefore well suited for validating the model. However, when comparing the annual outputs from the modules, the collected I_{sc} is utilized to calculate effective irradiance, E_e in the Sandia Array Performance Model [36], and used with the collected cell temperature to estimate the power production from each module.

E. Thermal model

The Sandia cell temperature model [36] was modified to predict the temperature of modules under low concentration. Thus, the thermal model utilized for this study is :

$$T_{Cell} = G_{DNI} \times C_0 + G_{diff} \times C_1 + \exp(C_2 \times G_{DNI}) + T_a \quad (20)$$

Coefficients were obtained using a least-squares optimization and were found to be $C_0=0.0232, C_1=0.0276, C_2=-0.00011$. These coefficients gave a Normalized Root Mean Squared Error (NRMSE) of 6% and a Mean Bias Error (MBE) of 0.1%. A correlation plot of this fit is shown in Figure 9

Interestingly, the measured data display temperature spikes for short periods during the day, where the cell to which the thermocouple was attached could reach temperatures approaching 100°C for a short period of time, as seen in Figure 10. One possible explanation is that these spikes are due to inconsistent illumination from the reflector, however the reflector is relatively uniform, and another possible explanation is that these temperature spikes are due to the normal "patch-work" appearance of cell temperatures for a short-circuited module, as shown in Figure 11.

Fig. 9: Correlation plot showing the quality of the fit of the temperature model.

Fig. 10: Thermal variations for May 29 and May 30, showing the thermal spike effect, and the fit of the proposed thermal model.

F. Model Validation

Initial validations were performed as comparisons to the solar simulator measurements described in section II-C. It was noted that the model accurately predicted the characteristics of a new Mylar ($m=0.03, \rho=0.73$) and Foylon ($m=0.07, \rho=0.84$) reflector as seen in Figure 12 and Figure 13. In addition, the imaging of the reflection onto the sensor is properly handled, as demonstrated by the matched uptake at 5° and 15° for $\theta_{included}=100^\circ$ and $\theta_{included}=90^\circ$, in Figures 12 and 13 respectively.

The model was then applied to the entire dataset, the model predictions are in reasonable accord with the experimental data, as shown in Figure 14. The prismatic glass module was fit with an NRMSE of 12% and an MBE of 1%, and the flat glass module was fit with an NRMSE of 14% and an MBE of 2%. Figure 15 presents a time series showing a typical fit of hourly data. It is important to note that beyond the tuning of the temperature model, no empirical parameters are utilized. All user inputs to the model were based on the physical properties of the system.

Fig. 11: *Top*: Two Infrared photographs of a module backsheet, with reflector augmentation taken 1 minute apart. A moving patchwork of hotspot cells is apparent. *Bottom*: view of multiple short-circuited modules. Only the modules highlighted with the white circle have reflector augmentation.

IV. EXPERIMENTAL RESULTS

Fig 16 presents the weekly normalized increase in P_{mp} between reflector and control modules. On average, the use of a non-tracking planar reflector can increase system performance for a module at the same angle (as characterized by $\int P_{mp}$) by 45% for a traditional flat glass module and by 40% for a prismatic glass module.

It should be noted that the high module angle of 57° is not the optimal non-augmented orientation for this latitude. An identical control module was mounted at 30° for the same period of testing, which is within 0.4% of the yearly energy yield of to the regional optimal angle of 35° . A Comparison of the energy output of the reflector augmented modules to this optimal control module gives an the energy performance increase of 18 % for both modules.

The effects of the reflector are also characterized in Figure 17, indicating the dependence of output ratio on solar zenith angle over the year for non-cloudy days for all modules.

Fig 18 displays a probability density function for module temperatures. It can be seen that for the majority of operation, the module operates below or near to Normal Operating Cell Temperature (NOCT), 48°C . There are some occasions where the cell temperature rises above 90°C , which is beyond the maximum design temperature of some commercial modules. The results of this study show that it is in the best interests of module manufacturers to ensure that segments of their modules can withstand elevated temperature operation in order to take advantage of the benefits of low-concentration system integration.

Fig. 16: Time series of daily power boost due to reflectors as compared to control modules, averaged over a one week period. The decrease in performance in July represents the time when the reflectors were reduced to horizontal in order to change the reflective material.

V. MODEL SENSITIVITY ANALYSIS

An optimization was performed to determine the best topology layout for the two typical reflector surfaces investigated in this study. It was assumed that the length of the module remained constant at 1m, due to manufacturing limits. The length of the reflector was also kept constant at 2.5m, it is assumed that this length of reflector could be reduced through optimization, however a large reflector which will not

Fig. 18: A probability distribution plot of cell temperatures, showing a slight increase in cell temperatures for reflector augmented modules.

introduce edge effects, was chosen for this optimization, and it is assumed that the output would not be largely affected by changes in reflector length around this ideal. Therefore, only panel angle (ω), reflector angle (ϕ) and the scattering coefficient (m) were optimized for a location in Kingston, Ontario, Canada (44° 14 0 N, 76° 30 0 W).

Combinations of ω , ϕ , and m were calculated within the domain:

$$\begin{aligned}\phi &\in [0, 10 \dots 60] \\ \omega &\in [25, 35 \dots 85] \\ m &\in [0.01, 0.04, 0.08, 0.15, 0.65] \\ \rho &= 0.8\end{aligned}$$

Note that the exact experimental apparatus is not included in this domain ($\phi = 20^\circ$ and 15° , $\omega = 57^\circ$), however the intention of this analysis is to sample the entire domain at regular intervals rather than to replicate the exact experimental apparatus, as was done in Section III-F.

The total boost, or increase in performance relative to a non-augmented module placed at the optimal orientation for the Kingston site (35°) was calculated for each case, and the results are shown in Figure 19. From this sensitivity analysis, it can be seen that the maximum theoretical increase in performance available is 30% over a non-augmented system. This is true for a variety of systems with an integrated reflectivity of 0.8, a scattering coefficient up to 0.08 and for a reflector angles between 30° and 40° .

It can be seen that there is a relatively low sensitivity to the overall module boost near the optimal point for each graph. However, the daily and yearly distributions of irradiance can vary by a large degree between different settings, which may be useful for load matching. Figures 20- 22 show the effects of varying ϕ , ω , and m from a base case of $\phi = 20^\circ$, $\omega = 55^\circ$ and $m = 0.01$

In order to identify if this form of system can be economically feasible, a rough economic case is presented. In this system, the simulated reflector length was approximately twice the length of the modules being simulated, thus 2:1 area ratio of reflector to module surface area is assumed. At a 2:1 area ratio, the distance between rows of PV modules would not be largely affected as compared to a non-reflector system. Thus, it is assumed that land costs will not make a

Fig. 19: Results of evaluation of the reflector code the simulation domain. The legend indicates the module angle (ω) in degrees, and each graph represents a different value of the scattering coefficient, m .

Fig. 23: Economic sensitivity analysis, showing the return on investment of the installation of a reflector system, as the cost of the reflector and system PPA rate are varied. This assumes an 8% cost of capital and 20 year project lifetime.

large difference in the economics of the project, and are not included in this analysis. The modules utilized in this system are $1\text{ m} \times 1.65\text{ m}$, or 1.65 m^2 , thus the equivalent reflector area is 3.3 m^2 . In a simple economic case, we will assume an interest rate of 8% over 20 years for the capital expense of the reflector system. The variables of interest are the installed cost of the reflector system, expressed in $\$/\text{ft}^2$, and the Power Purchase Agreement (PPA) rate received from the PV asset. From the results shown in Figure 23, the return on investment of installing a reflector system is highly dependent on the installed costs of the reflector. Further investigation is required to determine appropriate cost models for this component.

It should be noted that these estimations do not necessarily represent the overall economically optimal arrangement for a practical system where a DC overrate of 20%-30% is common. The optimal arrangement of reflectors will tend to increase the system output around periods of the day that already experience high levels of irradiance. Thus, much of the additional energy available from the reflector mirrors may not be utilized effectively by the inverters. Therefore, future work should investigate the optimal arrangement of a reflector system to ensure maximum inverter utilization.

VI. FUTURE WORK

As mentioned previously, future work should investigate the effects of DC overrate on the optimal arrangement of a reflector system. It is conceivable that the system could be optimized to maximize total energy yield, or could be optimized to produce more energy in the mornings and evenings in order to provide passive load balancing.

Another interesting extension of this work is to perform an optimization on the shape of the surface BRDF. Though the model used in this research represents a symmetrical BRDF, micro-engineered surfaces could be used to provide other non-symmetric BRDF profiles which could increase the effective output of planar concentrator systems. In addition this model should be adapted for solar thermal systems and photovoltaic solar thermal (PVT) systems, as the increased operating temperatures would increase the exergy [37]–[39] of both and decrease the spike annealing time of the latter [40], [41], increasing yields further.

Finally, an extension of the presented economic analysis is warranted to determine if the additional capital costs of the reflector system are warranted for both existing solar farms and retrofits.

VII. CONCLUSIONS

This analysis has demonstrated the use of a physically based BRDF model for evaluating the use of planar reflectors in low-concentration PV systems. The model provides a good fit to experimental data with an MBE of 1%-2% and an hourly NRMSE of 12%-14%.

From this analysis it can be seen that the use of non-tracking planar concentrators are a low cost method of increasing the performance of traditional PV systems. Over a year of outdoors testing, the system has been shown to improve energy yield (as characterized by $\int P_{mp}$) by **45%** for a traditional flat glass module and by **40%** for a prismatic glass module. Compared to a module oriented at the local non-augmented optimal angle, the experimental boost was seen to be 18%. A sensitivity analysis shows that at this latitude a maximum increase of 30 % is possible, with a reflector material having a hemispherical reflectance (ρ) of 80%.

In the future this modeling methodology can be used to optimize the reflector topology and identify the potential for increased energy harvest from both existing PV systems and newly built PV arrays.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the work of H. McLaren, J. Fairborn, Q. Bentley, D. Carter and A. Babasola and the support of the Sustainable Energy Applied Research Centre at St. Lawrence College, and to the forward-looking industry partners of this project who made it possible. This project was supported by the Natural Sciences and Engineering Research Council of Canada and a Social Sciences and Humanities Research Council of Canada grant.
